GENERAL EDI MA OF INDI TERMI NATE ITIOLOGY

REPORT ON THREE CASES

MELVIN W. BINGER, MD

AND

NORMAN M. KEITH, MD

ROCHESTER, MINN.

Occasionally we observe patients with edema who do not present clinical evidence of the pathologic conditions that usually produce edema. They do not have nephritis, for the conditions ordinarily observed in nephritis are not present. Nor do they have hypertension, myocardial degeneration with congestive failure, cirrhosis, polyserositis, myxedema or a malignant growth. The patients are usually well nourished and have been accustomed to a well balanced diet. No evidence of infection or toxemia is found, but there is a history of gradual progressive edema over a period of months that does not respond to the usual therapeutic measures. Except for the edema the patient feels quite well and on first impression one would make a diagnosis of lipid nephrosis.

On study, however, we find that there is no albumin in the urine, yet the value for serum protein is low, less than 5 Gm per hundred cubic centimeters, and the albumin-globulin ratio is altered in some cases. The plasma cholesterol is normal or low. The basal metabolic rate may be normal or slightly reduced. There is no clinical evidence of hepatic insufficiency and, usually, little or no digestive disturbance. Occasionally diarrhea of moderate degree is present. The blood count and value for hemoglobin may be slightly below normal, yet gross anemia is not present and there is no tendency to acidosis or alkalosis.

It is of interest to note that on analysis the edema fluid is similar to a transudate of the serum and very little protein is present. This is quite like the edema fluid obtained in cases of lipid nephrosis. In the last twelve years we have observed several cases of indeterminate edema and a brief clinical report of our earlier experience was made in 1932.¹

In the present paper we are reporting three cases. Thompson, Ziegler and McQuarrie in 1932 presented

a similar case that of a child and Myers and Taylor in 1933 reported the case of an adult in which there were similar manifestations.

REPORT OF CASES

CASE 1.—A man aged 62 gave a history of progressive weakness for five months. He had had a mild recurring diarrhea for five years. This diarrhea was without blood or mucus and was frothy in character. It was not severe enough to be disabling.

On examination he was found to have edema grade 3, with ascites and left hydrothorax. He was pale and emaciated. At the time of admission he weighed 136½ pounds (62 Kg) and at dismissal 99½ pounds (45.2 Kg) representing a loss of 37 pounds (16.9 Kg) of edema fluid in twenty-two days. He was somewhat anemic, the erythrocytes ranging from 3,200,000 to 3,750,000 per cubic millimeter, and the value for hemoglobin from 11.4 to 12.9 Gm per hundred cubic centimeters of blood. Studies of blood smears were negative.

As shown in table 1 the urea and sulfate clearances were below normal, denoting some degree of impaired renal function. Repeated tests of the urine showed little or no albumin and no sugar present. The serologic test for syphilis was negative.

A surprising observation in the absence of proteinuria was the low value for serum protein which ranged from 3.6 to 4.0 Gm per hundred cubic centimeters and the albumin-globulin ratio of 1:16. Although there was no clinical evidence of jaundice and the concentration of bilirubin in the serum was normal, the test of hepatic function showed dye retention of grade 2 to 3. It will be noted in table 2 that the value for cholesterol was unusually low, ranging from 75 to 83 mg per hundred cubic centimeters, and that the value for serum calcium was also reduced to 7.7. Basal metabolic rates ranged from -14 to -19 per cent, but in the presence of so much edema these were probably not true values. Certain other laboratory tests as shown in tables 1 and 2 were quite normal.

Examination of the stools which numbered from two to five daily while the patient was in the hospital, except for excess fat, were negative. Proctoscopic examination and roentgenologic studies of the colon were negative. Routine gastric analysis showed absence of free hydrochloric acid and a total acidity of 6 units, but fluoroscopic examination of the stomach and duodenum was negative. A roentgenogram of the thorax revealed left pleural effusion.

A diagnosis was made of an indeterminate type of edema, but because of hepatic insufficiency as indicated by the dye test and steatorrhea disease involving the liver and pancreas was suspected. The patient was given a salt-free diet with 2,000 calories, 800 cc of extra fluid and 60 Gm (later 100 Gm) of protein a day. He was given potassium nitrate 8 Gm a day, and during his stay of twenty-two days received three intravenous injections of mersalyl (0.5, 2 and 2 cc). Thyroid extract a total of 81 grains (5.3 Gm) was given him while in the hospital but without apparent effect. A total of 27 cc of liver extract was given intramuscularly with the idea of improving the condition of the blood although pernicious anemia did not exist. On the fourth day after admission edema fluid was obtained by needles from the legs. On the fifth day left pleural paracentesis was

performed and 250 cc of thin, clear, canary-yellow fluid was removed. This was negative on smear for bacilli of tuberculosis. Routine cultures were negative, and no malignant cells were found on smear of fluid from the thorax. The concentration of certain constituents of both edema and pleural fluids is given in table 3. The patient gradually improved and was dismissed three weeks after admission free from edema and with no demonstrable ascites or pleural effusion (fig 1). On

Fig 1 (case 1).—Increased excretion of urine and decrease in body weight during treatment

his return home however he gradually failed the edema and ascites returned, and he died a month later.

At necropsy⁴ the liver was found to be very slightly diseased, with some interstitial hepatitis (fig 2). There was little or no change in the kidneys (fig 3). The heart was normal in size and there was no gross evidence of disease. The spleen was normal. There was no demonstrable disease of the stomach or bowel. The pancreas (fig 4) however was practically destroyed. All sections revealed only a few ducts, moderately dilated and practically no acinous tissue was present, no islands of Langerhans were demonstrable. Between the ducts was dense connective tissue. There was no evidence of fat necrosis and no signs of any specific inflammatory process. The picture in the pancreas suggested very slight but continuous atrophy of the acinous tissue, such as might have been produced by complete and rather sudden obliteration of the main pancreatic ducts. Syphilis, tuberculosis, stone, suppurative pancreatitis and any sort of tumor or specific granulomatous process were apparently well excluded. There was sufficient anatomic basis to conclude that there was practically total pancreatic insufficiency, certainly of the acinous tissue and probably also of the islands, yet the patient evidently had not had diabetes.

CASE 2.—A married woman aged 35 first registered at the clinic Jan 3 1934. Her chief complaint was swelling of the face and lower part of the body and legs which had been present for approximately six months. Her family history was negative. She had had measles, diphtheria, scarlet fever and typhoid as a child. Menstruation had been normal. She had been married ten years and had two children both living and well. She had never had a miscarriage. She had always considered herself healthy. She had always had a good appetite and had always eaten a well balanced diet except that she did not like milk and never drank it.

Eight years previously following her first pregnancy which was normal, some pitting edema developed which persisted for three or four months. Her second pregnancy three years later was apparently normal and following this there was no edema.

With the onset of the edema in June 1933 there was no history of a cold, infection or other known cause for it. The patient's local physician found her hemoglobin to be slightly below normal, but other tests including those for nonprotein nitrogen and urea nitrogen in the blood, routine urinalysis and a determination of the basal metabolic rate, were normal.

The patient was given iron by mouth, and later the concentration of hemoglobin was 85 per cent. She was given a diet which contained a relatively small amount of salt and protein and extra fluid was restricted to 1000 cc a day. Numerous therapeutic agents were tried, including theocalcin "nephretin" ammonium citrate, mersalyl, theelin, "antutrin S," magnesium sulfate elaterin, thyroid, "pituitary extract" and a commercial adrenal extract. In spite of all treatment the edema persisted.

Physical examination at the clinic was negative except for the edema. The patient weighed 165 pounds (74 Kg). She did not appear anemic. Certain tests were carried out as noted in tables 1 and 2. A serologic test for syphilis was negative. The stools contained no parasites or ova. The fasting value for blood sugar was normal. The only outstanding abnormalities found were (1) a very low value for serum protein, with out inversion of the albumin-globulin ratio, this finding was especially significant when it was noted that the urine contained no albumin or other abnormal constituents, that studies of renal function gave normal results, and that the value for blood cholesterol was also normal and no lipid bodies were found in the urine, (2) a low value for serum calcium, which was

Fig 2 (case 1).—Section of liver showing moderate degree of fatty degeneration and some interstitial hepatitis (hematoxylin and eosin $\times 100$)

65 mg per hundred cubic centimeters and (3) no free hydrochloric acid on routine gastric analysis or with histamine, fluoroscopic examination of the stomach was negative.

Two small samples of edema fluid were obtained through a needle inserted in the lower portion of the leg. The fluid was clear as water as in the previous case and contained 0.1 per cent of protein (table 3). It resembled edema fluid of chronic lipid nephrosis, the blood simulated this condition in the low value for serum protein. As has been noted the urine contained no albumin or other abnormal constituents.

⁴ Drs. F. J. Hirschboeck, G. L. Berdez and F. W. Spicer of Duluth, Minn., sent the pathologic specimens and Dr. H. E. Robertson gave his opinion regarding these specimens.

The McClure Aldrich skin test resulted in a very rapid absorption of the injected salt solution. Roentgenograms of the hand and long bones of the arms and legs did not reveal osteoporosis. The value for plasma fibrinogen was increased to 680 mg per hundred cubic centimeters. A provisional diagnosis of an indeterminate type of edema was made, with low values for serum proteins as a result of some obscure metabolic disturbance.

A trial of certain therapeutic measures was indicated. The patient was given a carefully weighed diet, which was relatively

suggested a possible retention of protein nitrogen, although a concentration of blood due to loss of fluid might have produced these effects. There was also a loss of chloride and sodium but a retention of potassium and nitrate. With such distinct evidences of improvement the patient was dismissed from the hospital January 27 with the understanding that she was to continue the therapeutic measures as an outpatient and take her meals at the diet kitchen.

January 31 the serum protein and albumin had risen further to 4.4 and 3.3 Gm per hundred cubic centimeters respectively.

high in protein (from 80 to 100 Gm) and low in salt and water. Potassium nitrate was given because of its diuretic property, cod liver oil concentrate for its vitamin content, and calcium lactate in order to increase the calcium content of the blood and tissues. (For details see tables 1, 2, 3 and 4 and figure 5). On such a regimen, between January 8 and 24 (seventeen days) diuresis developed, the patient's weight decreased from 73.9 to 66.9 Kg (7 kg) and the edema practically disappeared. Examination of the blood revealed an increase in the number of erythrocytes and in the values for serum protein, albumin, calcium, potassium and nitrate, but a slight fall in plasma chloride. The value for serum sodium remained unchanged. The output of nitrogen in the urine compared to its intake in food together with a rise in serum protein

From then until February 27 there was no further increase but in fact a slight decrease. Because of failure of the serum protein to increase steadily, therefore, on February 20 the daily protein in the diet was increased from 100 to 125 Gm and a considerable amount of raw and cooked liver was also added. After a week on this diet, however, there was no appreciable rise in the value for serum protein. The patient had now been on a carefully controlled regimen for two months without, during the second month when up and about, having increased in weight or suffered from any distinct recurrence of the edema. Since February 5 the blood count and value for hemoglobin as calculated from the iron content and oxygen capacity had been at the lower limits of normal and in spite of the patient's apparent clinical improvement the value

for serum protein was still abnormally low. March 3, therefore, when she returned home, she was advised to continue the relatively high protein diet to take halibut liver oil concentrate in maximal doses, and calcium lactate 16 Gm daily. She expected to return for subsequent study in from four to six weeks.

At the time of the patient's second admission, April 6, 1934 her condition was practically the same as on the first admission except that she had less edema and weighed about 10 pounds less 155 pounds (70.3 Kg.) (table 2).

She was again given a carefully weighed, salt-free diet as before with from 100 to 125 Gm of protein a day, including

120 Gm of cooked liver and 600 cc of skimmed milk (purified casein was tried but found to be unpalatable). April 20, 1934, 500 cc of a 6 per cent solution of acacia (30 Gm) was injected intravenously. This evidently was an insufficient dose, but on account of the patient's small veins further injections were not attempted. On this regimen for eighteen days her weight increased 5½ pounds (2.4 Kg.), which was undoubtedly due to an increase in edema fluid. The serum protein also decreased slightly to 3.1 Gm per hundred cubic centimeters. Because of this failure of the patient to improve the following measures were instituted and continued for a month. Potassium nitrate was again given in daily doses of from 9 to 12 Gm (six to eight enteric-coated pills, containing 0.5 Gm of potassium nitrate each, were given three times a day after meals), 12 Gm of calcium lactate and 12 cc of diluted hydrochloric acid were also given daily for a period of twenty-seven days. Six injections of mersalyl (112 cc) were also given during this period. Fresh beef pancreas (120 Gm daily) was substituted for the cooked liver. The patient lost 12¾ pounds (5.8 Kg.) and became edema free. The concentration of serum protein rose to 4.1 Gm. The concentration of fibrinogen in the plasma had decreased to 430 mg per hundred cubic centimeters but there was no change in the volume of plasma or blood. This improvement we felt was due to the use of diuretics. The patient was dismissed May 26 and told to continue on the same diet, intake of fluid and medication, she was to discontinue, however, taking beef pancreas and was to take liver and other proteins instead.

On the patient's third admission there was no appreciable change, but on the fourth and fifth admissions gradual improvement was noted in her condition. She remained practically edema free and as noted in table 2 there was a gradual increase in the value for serum protein. She had taken from 8 to 12 Gm of potassium nitrate daily for the previous two years without any demonstrable toxic effects. She felt that her digestion was better when taking diluted hydrochloric acid and so was advised to continue its use. She was also to continue with 6 Gm of potassium nitrate daily for four days each week but gradually to discontinue its use entirely if the edema did not recur. In addition she was to continue with a diet low in salt but one containing 100 Gm of protein and an intake of fluid of 1000 cc daily. She has recently reported that she is doing well.

CASE 3—An unmarried woman aged 49 on admission complained chiefly of edema of her legs of three months duration.

As far as she knew she had been perfectly well until then except for the removal of a uterine fibroid in 1918. Edema first appeared in her ankles but then gradually increased and involved both legs, the lower part of her back and her abdomen. Except for occasional vague gastro intestinal upsets she had no uncomfortable symptoms.

On examination at the clinic she weighed 110 pounds (50 Kg.). The blood pressure in millimeters of mercury was 140 systolic and 90 diastolic. There was soft pitting edema of the legs and lower portion of the back and some edema of the eyelids. A small fibroid was present in the uterus but it was not thought to have any relation to the edema. There was no evidence of heart disease the lungs were clear, and the edge of the liver was not palpable.

As indicated in tables 1 and 2, the only abnormal laboratory finding was the low value for serum protein. As in the previous two cases, the urine was free of albumin, renal function was good and blood cholesterol was normal. The serum gave a negative flocculation test for syphilis.

Treatment consisted of a diet with 125 Gm of protein, and one high in vitamins, with moderate restriction of salt and an intake of fluid to 1500 cc daily. Because of the question of hepatic insufficiency as a cause of the hypoproteinemia, 1 cc of liver extract was given intramuscularly daily for six days. Whether or not this had any therapeutic effect is not known. Eighty-four grams of calcium lactate was given during the eight days in the hospital and 5 minims (0.3 cc) of viosterol was given twice a day. Ammonium chloride, 6 Gm, was given daily until the fifth day in the hospital, but because of a developing acidosis with a carbon dioxide combining power of the plasma of 38 this was changed to the same amount of potassium nitrate. The patient responded well and was free from edema at the time of dismissal.

TABLE 4—Observations in Case 2

First Admission Metabolism Study—Seventeen Day Period*		
Daily Mean Intake and Output in Urine		
	Intake	Output in Urine
Water	1,965 cc	1,963 cc

Serum nonprotein nitrogen mg per 100 cc	29	29
Chloride (as NaCl) mg per 100 cc	643	618
Serum sodium mg per 100 cc	257	296
Serum potassium mg per 100 cc	18	18§

* Diet calculated from Whelan's analysis and Sherman's tables. Daily mean content: Calories 2,125; protein 65 Gm; carbohydrate 205 Gm; fat 101 Gm; water 1,165 cc; nitrogen 10.2 Gm; chloride 1.47 Gm; sodium 1.23 Gm; potassium 3.22 Gm. Extra water 800 cc; nitrate nitrogen 1.0 Gm; potassium 3.29 Gm (the latter given as potassium nitrate). For thirteen days given calcium lactate 12 Gm. No diarrhea. The stools were formed and of normal color throughout.

† Total nitrogen eliminated after adding Folin and Wu tungstic acid solution for precipitating protein 10.9 Gm (mean of seventeen daily estimations). This indicates that the protein in the urine was scarcely measurable.

‡ Chloride calculated as chlorine

§ On eighth day 24 mg

COMMENT

In 1917 Epstein* first pointed out the fact that the extensive edema of chronic parenchymatous nephritis and chronic lipid nephrosis was related to the low concentration of protein in the circulating blood serum. The decrease in serum protein led to a fall in osmotic pressure so the fluid passed out of the blood into the tissues more readily. Epstein reasoned and we think logically that this loss of protein from the blood stream

5 Epstein A. A. Concerning the Cause of Edema in Chronic Parenchymatous Nephritis. *Medical Record* (Am J M S) 15: 638-647 (Nov) 1917.

was due to the marked albuminuria. Others⁶ have since thought that insufficient protein in the diet might be an added causative factor, because hypoproteinemia occurs in nutritional edema a condition seen in children, adults and experimental animals living on a sub-standard diet. Subsequent studies led us and others⁷ to believe that there were still other causes for the low

Fig. 3 (case 1)—Section of kidney showing normal appearing renal tissue (hematoxylin and eosin $\times 100$)

values for serum protein. Possibilities were (1) lack of digestion of protein in the small bowel and (2) loss of the organism's ability to manufacture serum proteins from the absorbed amino acids.

In the three cases reported herein the hypoproteinemia did not appear to be the result of loss of protein by way of the kidney, nor in the second case could it be attributed to an inadequate intake of protein. We were led, therefore, to consider the possibility of faulty protein metabolism. Several investigators⁸ have shown that experimentally produced hypoproteinemia leads to edema. Holman, Mahoney and Whipple⁹ have shown also that the recovery of concentration of serum proteins in the dog occurs at different rates after the ingestion of different types of protein. Myers and Taylor³ noted in their case that a high intake of protein

180 Gm daily for eight weeks, failed to cause a rise in plasma proteins. Even the introduction of blood serum into dogs¹⁰ and human beings¹¹ with hypoproteinemia by means of transfusion has not always resulted in a permanent increase in the concentration of serum protein. Study of our first patient, who had a destructive lesion of the pancreas, suggested the possibility that lack of pancreatic secretion, and hence insufficient digestion of protein might be the cause of the edema. The feeding of fresh beef pancreas to the second patient had no demonstrable effect.

There is much in favor of the assumption that the liver is the site of formation of serum proteins. In the case of Thompson, McQuarrie and Bell¹² the liver at necropsy showed widespread atrophy of the hepatic cells. On the other hand the minimal pathologic changes found in our case 1 did not seem significant, but of course the absence of distinctive and definite histologic alterations does not rule out the possibility of some abnormal hepatic function. Nor does the lack of response to liver therapy as carried out in our cases permit us to conclude that some function of the liver is not disturbed. At present there does not seem to be enough direct evidence to prove that the liver is the sole site of formation of serum proteins. The signifi-

temia in case 2, for example, was due to failure of digestion of protein within the intestine or to an inability of the organism to synthesize protein from the amino acids in the blood stream. It is possible, but does not seem likely, that vitamin deficiency played a causative role in these cases for patient 2 received a diet rich in vitamins for two months without a distinct rise in serum protein.

It is important to point out that Amberson and his colleagues¹³ have demonstrated that in the dog and

Fig 3 (case 2)—Diuresis and decrease in weight during treatment

cat the blood serum can be removed and almost entirely replaced by acacia in Ringer's solution without a resulting serious physiologic disturbance. In their experiments serum protein was manufactured at a rapid rate and a normal concentration was reached in from four to eight days. Such facts indicate that the most obvious function of the serum proteins is their physical action of maintaining an adequate osmotic pressure and viscosity. Hartmann and his associates^{11b} have shown that restoration of serum osmotic pressure can be accomplished clinically with acacia if it is given intravenously in sufficient concentration. Our immediate results with augmentation of protein and limitation of sodium chloride and fluid in the diet and the use of diuretics have been favorable and we have not felt it necessary to give acacia in large amounts or blood transfusions as therapeutic aids.

We realize that these cases are rare. The results indicate that hypoproteinemias can be an extrarenal disturbance and a difficult therapeutic problem. Further studies in similar cases should offer an excellent opportunity to advance our knowledge of the complicated equilibria present in nephritic and nephrotic edema.

After this article had been written we were informed of two previous reports of cases similar to those with which this paper is concerned.¹⁴

FRACTURES AND DISLOCATIONS OF THE CERVICAL SPINE

FIRST AID AND TRANSPORTATION

THEODORE PREWITT BROOKES, M.D.

ST. LOUIS

In previous publications I have discussed some predisposing causes of dislocations of the neck¹ and the complications encountered in their treatment.² The title of this paper was suggested by an experience related by an officer of the army while he was a surgeon of the Otacuta District of the Civilian Conservation Corps. From his office window he saw an injured man alighting from a truck. The man hobbled on a stick dragging one foot. He held his head tilted toward one shoulder with his chin rotated to the opposite side. The procession was halted and it was learned that the man had fallen from a tree and had been transported over the rough trails and roads of the district for a number of miles. The history and gross appearance of the man were typical of injury to the cervical spine. The officer ordered him on a stretcher and to the hospital at once. Further examination revealed compression of one of the lower cervical vertebrae and rotary dislocation of the vertebrae above this level.

Reviewing my own series of ninety patients with dislocation of the neck seen during the last seven years, I find that twenty-one were transported distances varying from 5 to 300 miles. In ten of the twenty-one cases the condition was acute and serious with involve-

ment of the spinal cord or spinal nerve trunks. It was an exception to see a case in which my attempt had been made at adequate immobilization. I have seen an army officer with a known fracture and dislocation of the cervical spine walk through the midway of a railroad station. His head was rotated and laterally flexed.

From the Department of Surgery, Washington University School of Medicine.

Owing to lack of space this article is abbreviated in *THE JOURNAL* by the omission of several illustrations. The complete article appears in the author's reprint.

2. Brookes T P. Dislocation of the Cervical Spine. Their Complications and Treatment. *Surg. Gynec. & Obst.* 57: 772 (Dec) 1933.

His right forearm was supported by his left because of weakness due to pressure on cervical nerve trunks (figs 4-7). Such incidents should not occur. Modern treatment of fractures has emphasis on early mobilization and resumption of function, but the cardinal principle of early care is accurate and absolute immobilization.³ This is particularly important in injuries of the spine because of the imminent menace to major nerve structures.

Fig 1 (case 84)—Incomplete lateral dislocation. A boy aged 13 years was struck by an automobile eleven days prior to my seeing him with Dr. Roland S. Kieffer. No demonstrable nerve injury was found. Anteroposterior and lateral x-ray films by Dr. Joseph Peilen showed elevation of the right lateral mass of the sixth cervical vertebra with a left lateral slip. No anterior displacement was visualized.

Principles of first aid preparatory to transportation are threefold. First, movement must be reduced to a minimum. "Splint them where they lie" is the army's dictum for all fractures.⁴ Facilities for immobilization must be brought to the patient and not the patient to the splint. Nowhere is this more important than in spinal injuries. Second, the patient should be put in a proper position for moving. Injuries to the thoracic and lumbar spine require that the patient be placed on the abdomen, but in injuries to the cervical spine he must be laid on his back with his head and neck fully extended. When a patient is placed on the litter, one person's entire attention must be given to supporting and keeping in alignment the head and neck. Third, immobilization must be such as to preclude flexion, lateral bending and rotation of the head. An ingenious home-made adjustable collar has been designed by Chamberlin.⁵ A simpler and more accurate mechanism is described by Wright.⁶ It is not probable that such appliances nor yet materials with which to make them will be available when needed. Simpler devices must be employed. Dr. Phil Hoffman cuts an emergency Thomas collar from two or more thicknesses of felt and fastens them snugly about the neck. To this may be added a stockinet slipover for skin comfort. Tapes for ties are fastened on the felt with adhesive plaster. But saddle felt is a rarity these days, particularly in the military services.

Sandbags, three-fourths full and placed on both sides of the head and along the shoulders, give good temporary splinting. The old pillow splint has long been

a standby for early immobilization of fractures. It can be employed in injuries of the neck, pillows being packed alongside the head to fill in tightly the angle between the head and the shoulders. Whether one uses sandbags or pillows, a small firm pad must be placed under the midcervical region to sustain the natural cervical curve. In the presence of severe tearing of soft tissues about the spine, a drooping cervical curve will cause grave distress and may actually pinch the cord by pressure of the sagging odontoid process. I doubt that adequate traction apparatus can be applied for transportation.

In addition to damage to the bones in fracture or dislocation of the neck, there is always involvement of soft tissues. Intervertebral disks are contused or compressed. Capsules or ligaments are stretched and torn. Damage to the nerve tissues is variable. The spinal cord has ample space in the cervical canal to permit a remarkable range of movement. Spinal nerves are marvelously shielded by bony arches as they emerge from the spinal canal. The maximum damage is done at the moment of impact. With the release of the causative force, fractures and dislocations tend to accomplish a certain amount of spontaneous replacement. Accordingly the degree of dislocation or amount of fracture found at the time of examination does not indicate the amount of damage to the cord or nerve trunks. Despite freedom of movement and bony protection, the cord may be irreparably damaged at the moment of injury, yet the dislocation may so completely reduce itself that no evidence is found on the x-ray film. Serious damage to an intervertebral disk does

Fig 2 (case 84)—Oblique views bring out clearly the mechanism of the displacement. The right inferior articular process of the sixth cervical vertebra is elevated and caught on the tip of the superior articular process of the seventh. There is a definite lateral slip of the left articular process of the sixth. Reduction was carried out under a methylcyclohexen methyl barbiturate acid anesthesia. Taylor traction and manipulation being used. The part was immobilized in a plaster of paris cast. Complete recovery resulted. The patient left the hospital wearing a celluloid doll collar seven weeks after reduction.

not always show on early examinations. It may require weeks or months before such an injury is demonstrable in roentgenologic study.⁸

Some incomplete subluxations of cervical vertebrae are better diagnosed by clinical examination than by

roentgenologic films. However, no intelligent surgeon will care to attempt treatment of such injuries without adequate x-ray study. Ample films and close study by roentgenologist and surgeon give an increasing percentage of accurate diagnoses.⁹ Routine x-ray examinations call for three exposures, a lateral view of the cervical spine and two anteroposterior views, of which one is taken through the open mouth to show atlanto-axial relationships. In doubtful cases stereoscopic

Fig 3 (case 77)—Severe unilateral rotary dislocation. A woman aged 49 was in an automobile that turned over thirty-six hours before Dr Kieffer and I saw her. She was completely paralyzed below the shoulders. X-ray films by Dr Arthur E. Echternacht show rotary dislocation of the sixth cervical vertebra, the right side being displaced until the body lies sharply angled in front and to the right of the seventh. The right inferior process of the sixth has jumped over the superior process of the seventh and lies locked in the intervertebral notch. Under n-methyl cyclohexen-methyl barbituric acid anesthesia the dislocation was completely reduced and immobilized in a cuirass. During the third week she regained motion in the legs and thighs. Early in the fourth week she suddenly showed evidences of pulmonary embolism and died. Figures 3, 4, 5, 6 and 8 are from x-ray prints accurately retouched by Mr P. A. Conrath.

views are taken both laterally and anteroposteriorly. Oblique views bring out the relationship of articular processes in startling fashion and are of great assistance in difficult cases.

Fractures complicating dislocations may be actually life saving in effect, as in case 85 (figs 8-10) in which the pedicles of the bony ring gave way, allowing the body of the vertebra to displace completely while the posterior arch held to the intervertebral ligaments and shielded the cord from severance or crushing. If the ring had followed the vertebral body it would have guillotined the cord.

Dislocations, with or without demonstrable fracture, constitute a major emergency demanding immediate and positive treatment. The first step is closed reduction. It is agreed by surgeons seeing more than an occasional case of this sort that open operation has no place in the treatment of acute injuries to the cervical spine.¹⁰ Laminectomy removes the posterior pressure but leaves the cord angled over the displaced vertebra. It precludes later reduction for callus formation will not permit successful replacement at a later date. I doubt whether the Queckenstedt test is of decisive

value in first treatment. The patient should not be rolled sufficiently to make a satisfactory test in the first place. In the second place the dislocation should be reduced at once whether or not spinal block is present. After reduction and immobilization it is safe and helpful to have such evidence of the state of the cord.

A few lesser dislocations, or subluxations, can be replaced without anesthesia, but the vast majority require full general anesthesia. Any of the inhalation anesthetics answer well. I have used n-methyl-cyclohexen-methyl barbituric acid intravenously on occasion when inhalation narcosis was contraindicated. I have found the Taylor technic¹¹ of immediate traction and manipulation to be the safest and surest in handling recent fractures and dislocations. The Walton maneuver¹² of retrolateral flexion and extension has been of great aid in unilateral or rotary dislocations, particularly the old, neglected cases. It is too severe for fresh cases in which fracture is known or suspected to exist. An additional advantage of the Taylor method is that the head halter and traction belt enable the operator to maintain full extension during the application of a plaster-of-paris cast.¹ A carefully applied plaster

Fig 8 (case 85)—Extreme fracture dislocation. A man aged 65, a carpenter, fell from a roof to the ground, a distance of 10 feet. He picked himself up and walked into the office of his family physician, Dr A. W. Westrup, who sent him in an ambulance to the hospital. X-ray films by Dr Joseph Peden show: 1. Complete anterior dislocation of the upper five cervical vertebrae. The body of the fifth cervical vertebra is tilted through an arc of 90 degrees until its horizontal surface lies vertically against the perpendicular face of the sixth. 2. Fractures through pedicles of the fourth and fifth. 3. Locking of lower articular processes of the fourth in front of superior articular processes of the fifth.

cuirass gives the safest and surest immobilization. Even in cases in which there are extensive paralyses a cuirass insures the maximum chance of recovery and

greatly simplifies the nursing care. The patient can be moved about in bed or transferred to another bed without undue risk.

Other forms of splinting offer many disadvantages though they may be necessary under exceptional circumstances. Sandbags about the head and neck will be constantly moved by the patient or the attendants.

Fig 9 (case 85)—Oblique view again shows that the inferior articular processes of the fourth cervical vertebra have jumped over the superior articular processes of the fifth and lie in the intervertebral notch wedging the fractured posterior arc of the vertebral ring away from the body of the vertebra. It was impossible on the first attempt to secure more than partial replacement. The patient's condition became worse and the part was immobilized in a plaster corset for forty eight hours.

The jury-mast apparatus or the suspension of the head and traction over the end of the bed by means of chin strap¹³ or ice tongs in the outer table of the skull¹⁴ or fishhooks under the zygomatic arches¹⁵ will not immobilize. Limited flexion and large rotation are possible in all these appliances. The head must be kept quiet. Motion may further damage nerve tissues. Motion interferes with accurate union and furthermore motion stimulates excessive callus formation, which will encroach on the exits of the spinal nerves, producing permanent pain and disability.

In his delightful monograph "On Rest and Pain," Hilton¹⁶ devotes a chapter to spinal injuries treated by rest. Without the aid of x-ray examination or other modern diagnostic means his description and analysis of cases remains a classic. He cites relief of symptoms and cure of paralysis after traumatic spondylitis by absolute immobilization. His facilities for immobiliza-

tion were limited. Today, with modern equipment and simple plaster-of-paris bandages, there is no excuse for not making use of this best form of splinting following reduction. Redislocation¹⁷ the result of inadequate immobilization occurs less frequently, I believe, when a proper plaster-of-paris cast is applied.

The plaster corset must be applied accurately. The operator will require trained assistants for after reduction he will be occupied with maintaining the head in position of full extension with the articular processes thoroughly seated home on underlying facets. If the patient's injury and condition permit, stockinet or jersey tubing is applied in two sections. One is a shirt from the neck to the waist and one is a hood over the head with anterior and posterior skirts to be fastened to the shirt with adhesive plaster. Pressure points such as the shoulders, the thyroid area, the chin and the back of the occiput are padded with pieces of felt. Sheet cotton is applied over all smoothly, without wrinkles and only in sufficient thickness to line the cast. The felt takes care of pressure points. Cotton of too great thickness allows the patient to move about within the cast and defeats its purpose. Careful reinforcement by plaster splints or slabs over points of stress will permit the total weight of the cast to be kept at a minimum.

Fig 10 (case 85)—Result of first attempt at replacement. Body of the fifth cervical vertebra has been lifted up onto the sixth but cannot be brought back by reason of the block produced by articular processes of the fourth lying in front of the articular processes of the fifth rather than in their normal position.

Incorporating tapes in the plaster for constant traction at the same time that rigid immobilization is maintained has been suggested¹⁸. This may be useful when separation of the injured vertebrae is necessary. It should be remembered however, that immediate and

¹⁸ Bisgard J. D. A Device for the Simultaneous Traction and Complete Immobilization of the Cervical Spine J. Bone & Joint Surg. 14: 190 (Jan.) 1932.

complete reduction is the proper procedure. Once reduction has been secured, the head is kept in full extension and the vertebrae are allowed to rest in normal relationship to one another. It is important that vertebral bodies have only a normal amount of separation as afforded by intervertebral disks, also that articular processes are not separated but are completely seated home on the underlying facets. Excessive callus formation is minimized by close approximation of injured surfaces.

After-care demands all the watchful detail of other severe bone or nerve injuries. Development of pressure sores and trophic skin disturbances must be watched for and avoided. The patient's morale calls for stimulating psychotherapy. Patient 85 (fig 11) was unable to swallow for weeks and had to be fed by means of the nasal tube. Patient 77 (fig 3) with

Fig. 11 (case 85)—Final complete reduction of bodies and processes of cervical vertebrae accomplished forty-eight hours after the first attempt. Taylor traction and manipulation was used. A plaster of Paris collar was applied. It was necessary to feed the patient by way of the nasal tube. He was unable to swallow at all. The voice was husky. After six weeks he began to swallow semisolids such as cereals and custards but still struggled on liquids. Apparently the recurrent laryngeal nerve was damaged and probably the muscles of deglutition were torn. Drs. C. A. Stone, A. W. Westrup and K. V. McKimsey collaborated and assisted in this case.

complete paralysis below the shoulders, regained motion in the legs during the third week but suffered pulmonary embolism in the fourth week and died. Patients with cord injury will have either incontinence or the opposite condition of retention of urine and feces. A particular menace in high cord paralyses is inability to cough or clear the throat. The patient may strangle in his own secretions. An aspirator of some sort must be kept ready for immediate use if mucus collects in the throat. Despite the utmost care there will be disappointments, but the percentage of gratifying results remains in proportion to the accuracy of early reduction and the details of post-reduction attention.

ROENTGENOGRAPHIC DIAGNOSIS AND ANATOMIC STUDIES OF A QUINTUPLE PREGNANCY

E. C. HAMBLÉN, M.D.

R. D. BAKER, M.D.

AND

G. D. DERIEUX, M.D.

DURHAM, N. C.

Quintuple pregnancy is expected about once in forty million births according to calculation by the Hellin ratio.¹ Foster and Carson² collected thirty-two authentic reports of quintuplets from the literature up to 1923. Since that time we have found reports of two more,³ including the Dionne quintuplets. Ours makes the total of reported cases thirty-five.

Aside from the fact that such multiple pregnancies are interesting because of their infrequency, a report of our case seems justified since it is apparently the first instance of a diagnosis being made prior to delivery. Further interest lies in a complete anatomic study of the fetuses, placenta and membranes.

REPORT OF CASE

Clinical Record.—A white woman, aged 20, was admitted to Duke Hospital, Nov. 2, 1936, because of hydramnios and irregular vaginal bleeding complicating a pregnancy of approximately five months' duration.

The past history of the patient was essentially unimportant except for the fact that her first pregnancy had ended in a spontaneous abortion at three months, the recovery from which was complicated by a mild infection. No positive history was obtainable in reference to the occurrence of multiple pregnancies on either the maternal or the paternal side of the family.

The pregnancy had progressed normally until two weeks prior to the time of admission when the patient first observed mild uterine contractions accompanied by slight vaginal bleeding insufficient to saturate a pad. During the two weeks prior to admission she had noted a rapid increase in the size of the abdomen which had resulted in marked dyspnea on exertion. One week before admission she had experienced another slight episode of vaginal bleeding.

On examination in the hospital the abdomen appeared abnormally large, the fundus uteri extending 33 cm. above the symphysis. The circumference of the abdomen was 50 cm. The fetal outlines could not be identified and the fetal heart sounds were not heard.

The blood pressure was 124 systolic, 86 diastolic. There was moderate secondary anemia; hemoglobin was 65 per cent by the Sahli method and the red blood cells were 2,950,000. The Wassermann and Kahn reactions were negative.

A roentgenogram of the abdomen in the lateral position showed the presence of four fetal heads and five bodies (fig. 1).

On the second day after admission the patient began to have irregular uterine contractions, which resulted shortly in a profuse vaginal hemorrhage. About 300 cc. of blood was lost in an hour's time. Examination of the abdomen at this stage showed no boardlike rigidity and the patient did not complain of severe pain. Sterile vaginal examination revealed the cervix slightly dilated with a fetal head overlying the internal os. The placenta was not felt. There was about 100 cc. of clotted blood in the vagina. Since the uterine bleeding continued and the pulse rate rose to 120 per minute induction of labor was elected. The presenting membranes were ruptured and about 200 cc. of amniotic fluid was evacuated. A Voorhees bag was inserted.

From the Department of Obstetrics and Gynecology and from the Department of Pathology, Duke University School of Medicine and Duke University Hospital.

After twelve hours of uneventful labor, four of the premature fetuses were born in rapid succession by cephalic presentation. The fifth, an anencephalic monster was delivered without difficulty. Heart action in two fetuses continued for thirty minutes after birth. The placenta was expelled normally. There was no postpartum hemorrhage. The puerperium was uncomplicated. The patient was discharged from the hospital on the twelfth postpartum day.

Anatomic Studies—Placenta The placenta measured 22 cm long 17 cm wide and 2 cm thick. It was oval. There was a hematoma 6 cm in diameter at one end. Inspection of the maternal and fetal surfaces showed no evidences of subdivision.

Membranes (fig 2) The chorion extended irregularly from the edge of the placenta. In some areas it could be traced for as much as 6 cm from the placental border. There was apparently a separate amnion for each fetus. No extension of the chorion was identified along the amnions. Three of the umbilical cords were traced readily to the placenta; a fourth one had been detached but its attachment at a confluence of vessels was located. The monster, which was provided with an imperfect amniotic sac, could not be related exactly to the placenta. A piece of chorion, however, at the end of its atrophic cord seemed to correspond to an area on the nonplacental portion of the chorion situated not far from the position of fetus 1 (the system of numbering of the fetuses is described later). Four of the cords were attached toward the periphery of the placenta.

A peculiar yellow flat body about 0.5 cm in length was encountered on the chorion in the more central part of the placenta at the end remote from the hematoma. This was thought to be a yolk sac. Similar smaller bodies were observed in the amnions of fetuses 3 and 4.

Anastomosis of Vessels The fetal aspect of the placenta contained anastomotic vessels often quite small and running between all the identified points of attachment of the umbilical cords.

Fetuses Numbering clockwise from the monster (fig 3) the crown-rump lengths and the weights after fixation were as

Fig. 1—Antepartum appearance of the quintuple pregnancy. Four fetal heads and five bodies are shown.

follows: fetus 1, 15 cm, 199 Gm; fetus 2, 14.5 cm, 198 Gm; fetus 3, 15 cm, 192 Gm; fetus 4, 16 cm, 254 Gm; fetus 5 (monster), 5 cm, 120 Gm.

The umbilical cords of the four well formed fetuses varied in length from 26 to 31 cm. That of the monster was only 2.5 cm in length and its diameter was less than that of the others.

The four well formed fetuses had the same number of digits and showed no peculiarities which distinguished them aside from the fact that one was larger than the others. Comparison between the monster and the four well formed fetuses showed in addition to the more obvious points of dissimilarity, only four digits in the left lower extremity of the monster. No

upper extremities or facial features were identified in the monster. The skull was completely missing. The right lower extremity was an abortive structure resembling a malformed foot. The monster represented apparently only one individual.

Sex of Fetuses The four well formed fetuses had similar genitalia. Comparison of these genitalia with the observations of Spaulding⁴ showed these to be of female type. The

Fig. 2—Single placenta and separate amnions of the fetuses (before fixation). The amnion of the monster had been removed for the most part. Note the hematoma adjacent to the monster and the yolk sac at the opposite end of the placenta.

abdominal cavity of one of these fetuses was opened. Uterus, tubes and ovaries were present. An ovary and tube were taken for microscopic study.

The external genitalia of the monster were like those of the other fetuses but were more rudimentary. Section of the abdomen failed to reveal definite pelvic organs; however, a structure thought to be an ovary but smaller than the one that was obtained from the well formed fetus was located. This was removed for microscopic study.

Microscopic Study The ovaries from the well formed fetus and monster showed ova and a few small follicles. The body thought to be a yolk sac showed amorphous granular material which stained with hematoxylin and was probably calcium.

COMMENT

Aside from the infrequent occurrence of quintuple pregnancy, the chief interest in the reported case lies in the fact that the diagnosis was made from the roentgenogram and that the circumstances allowed a complete anatomic study of the fetuses, placenta and membranes.

In our review of the literature, no instance of the diagnosis of quintuple pregnancy prior to delivery was encountered. As Greenhill⁵ has observed, there are four authentic reports of such diagnosis in quadruple pregnancy.

It seems reasonable to assume that the hydramnios and the premature partial separation of the placenta

⁴ Spaulding, M. H. The Development of the External Genitalia in the Human Embryo. Publication 61. Contributions to Embryology. Carnegie Institution of Washington 13: 67, 1921.

⁵ Greenhill, J. P. Correspondence. Am. J. Obst. & Gynec. 22: 903 (Nov.) 1936.

both of which conditions necessitated interruption of the pregnancy, were associated with the presence of the anencephalic monster. The hematoma described in the anatomic studies was related to the attachment of the monster. The short cord of this monster was no doubt a factor in this hemorrhage, the mechanism of this being, perhaps, rupture or detachment.

The chief discussion provoked by the anatomic studies is in regard to whether this pregnancy was uniovular or multiovular.

When a single placenta occurs in a multiple pregnancy, several criteria have been laid down to determine whether the pregnancy is derived from a single ovum

be accepted as unequivocal evidence. The number of corpora lutea is a valuable clue in the case of species which ordinarily discharge a single ovum but in other forms is usually without diagnostic value, because of the variable and unknown factor of egg mortality.

These remarks regarding twinning should apply also to other instances of polyembryony. Our quintuplets were in a comparatively late stage of development and hence the single chorion cannot be thought to be proof of identity of the fetuses. One yolk sac was apparently found and possibly three, but none seemed to be common to two or more fetuses. Since no examination of the ovaries of the patient was possible, evidence derived from the number of corpora lutea was not available.

We feel inclined to conclude from this consideration that the pregnancy may have well been derived from a single ovum, but a definite statement cannot be made on this point.

THE DEVELOPMENT OF ACUTE HEMOLYTIC ANEMIA

DURING THE ADMINISTRATION OF SULFANILAMIDE
(PARA-AMINO BENZENESULFONAMIDE)

BALTIMORE

Fig. 3—Cord attachments (after fixation)

or not. Among the more important of these are the presence of a single chorion, the anastomosis of blood vessels among the various cord attachments and the similarity of fetuses with regard to sex and peculiarities of structure.

Our case apparently exhibited a single placenta, a single chorion and anastomoses between the various cord attachments. All the fetuses were of the same sex.

Hamlett and Wislocki⁶ have called attention to the inadvisability of designating twins as being identical in nature simply because of the presence of a single chorion. They say:

We wish to discard the term 'monochoorial twins' since such individuals may often be the result of fusion of separate ova. A common yolk sac would appear to be absolute proof of the identity of twins but a common chorion in late stages cannot

The use of sulfanilamide (para-aminobenzenesulfonamide) in the treatment of various bacterial infections, notably those caused by the hemolytic streptococcus, is rapidly becoming widespread owing to the favorable reports published first by Domagk in Germany,¹ then by Colebrook in England,² and recently by Long and Bliss³ in the United States. Certain minor toxic effects of the drug have been noted, namely, a depression of liver function as determined by the bromsulfalein excretion test, fever, cyanosis and mild acidosis,⁴ but thus far no toxic effects of alarming proportions have been described in the literature. That a drug with such close chemical relationship to aniline might have a very serious effect on the blood and bone marrow has undoubtedly been in the minds of many, and in this clinic patients have been rather carefully watched for the appearance of such phenomena. During five months of intensive use of sulfanilamide in the treatment of streptococcal infections nothing untoward occurred and, until the cases of hemolytic anemia to be reported here were observed, this new drug, potentially so toxic, seemed to be a relatively innocuous therapeutic agent as far as the patient was concerned.

However, within a few weeks three cases of severe hemolytic anemia were observed in the wards of this hospital, two occurring during the treatment of streptococcal sore throat and one during the treatment of meningococcal meningitis with sulfanilamide. So far we have not been able to prove conclusively that the drug was responsible for the rapid hemolysis, but since no previous cases have been noted in this hospital with

From the Medical Clinic of the Johns Hopkins Hospital and University. Dr. E. K. Marshall Jr. helped in the study of these cases and Dr. Hugh Josephs gave advice and assistance in the study of urobilin excretion.

similar infections and a fourth case of hemolytic anemia has occurred in this city during the administration of sulfanilamide it seems fairly certain that the drug in some manner was responsible for the hemolytic crises. We feel that it is most important that these cases be reported so that physicians using sulfanilamide in the treatment of seriously ill patients may be on the lookout for such a dangerous complication.

Fig 1 (case 1)—Results of blood studies in case of streptococcal sore throat.

REPORT OF CASES

CASE 1—A Negro chauffeur, aged 36, admitted to the Johns Hopkins Hospital, March 15, 1937, complained of an acute follicular tonsillitis. In general his health had been good in the past. He had typhoid at the age of 6 years and in 1922 a peritonsillar abscess, which was incised. Since childhood he had had frequent mild sore throats of from two to three days' duration, the last of which was one year before his present illness. Two days before entry he caught a head cold. The following day he noted a scratchy sensation in the throat and he had a slight chill. The sore throat grew worse and he came to the hospital for treatment.

The temperature was 104 F, pulse 110, and respiratory rate 40 per minute. The patient did not look severely ill. The general physical examination revealed very few abnormalities. The mucous membranes were of good color, and cyanosis or jaundice was not noted. The tonsils were enlarged and red and were covered with flecks of yellowish exudate. A few tender glands were palpable at the angles of the mandible. The heart was not enlarged. A soft systolic murmur was audible over the whole precordium. The lungs were clear to percussion and auscultation. The liver and spleen were not palpable. The patient weighed 68 Kg (150 pounds).

The laboratory examinations revealed the following: Urine specific gravity, 1.003, albumin, sugar, diacetic acetone and bile negative; urobilin 3 plus; sediment normal. Blood: red blood cells 4,900,000, hemoglobin 101 per cent, white blood cells 19,000, of which 82 per cent were adult polymorphonuclears, 3 per cent juvenile neutrophils, 10 per cent lymphocytes and 5 per cent monocytes.

In the smear the red blood cells were normal in size, shape and hemoglobin content. The platelets were numerous. There was no sickling of the red cells immediately or after twenty-four hours.

The Wassermann reaction was negative.

The throat culture showed 95 per cent beta hemolytic streptococci.

The patient was given 4.8 Gm of sulfanilamide by mouth and at the end of four hours the concentration of the drug in the blood was 10 mg per hundred cubic centimeters. For the next two days the dose of sulfanilamide was 0.9 Gm every four hours, and after this the amount was lowered to 0.6 Gm every four hours.

The throat infection cleared up rapidly, and the temperature and white blood cell count dropped to normal on the third day of his hospital stay. During this period he complained of dizziness and nausea, and it was noted that his lips were slightly blue. On the fifth day of sulfanilamide medication, after two days without fever, a temperature of 102.6 F developed. It was thought that this was due to the drug which was promptly discontinued. The following day he complained of severe headache and was quite drowsy and weak. He perspired continually, and the mucous membranes were discovered to be very pale and definitely icteric. An examination of the blood revealed at this time a red blood cell count of 1,570,000 with only 30 per cent hemoglobin. There was a marked leukocytosis with 87,000 white blood cells, of which 1 per cent was myeloblasts, 20 per cent juvenile neutrophils, 53 per cent polymorphonuclear neutrophils, 2 per cent eosinophils, 14 per cent lymphocytes and 7 per cent monocytes. The smear showed numerous nucleated red blood cells, much polychromatophilia, and reticulocytes of 20 per cent. Platelets were very numerous. The urine contained large amounts of urobilin but no bile or hemoglobin. The fragility of the red blood cells was normal. In spite of the jaundiced appearance of the patient the van den Bergh reaction of the blood showed only a slight trace of bilirubin. The non-protein nitrogen was 32. A bromsulphalein test of liver function resulted in 30 per cent retention of the dye thirty minutes after injection. A phenolsulfonphthalein test of kidney function showed 50 per cent excretion in fifteen minutes and 77 per cent at the end of two hours.

Fig 2 (case 1)—Blood smear showing anisocytosis and central achromia of the red blood cells. Two nucleated red cells and a myelocyte are present in the field.

The patient was given three transfusions of citrated blood of 500 cc each during the next forty-eight hours, and his condition improved rapidly. The results of the repeated blood studies during his convalescence are shown in figure 1. The hemoglobin and red blood cell count increased rapidly, and the marked evidences of regeneration of the erythrocytes as revealed by the many reticulocytes and nucleated red cells.

gradually subsided. The striking leukocytosis fell slowly to a normal count, and mature cells soon replaced the young forms.

During the recovery period he had an exacerbation of the streptococcal sore throat which caused no apparent delay in the return of the blood picture to normal.

CASE 2—A Negress, aged 26, a housewife, entered the Johns Hopkins Hospital, March 24, 1937 for treatment of a peritonsillar abscess. Her past health had always been good. In 1933 she had a severe sore throat with marked swelling of the tonsillar lymph nodes. She had recovered within a few days and remained in good health until December 1936, when a similar difficulty developed, which was less severe in nature.

Four days before her admission the throat became sore and she was unable to swallow solid food. Two days later the pain was so great that liquids could not be taken and she finally came to the hospital for treatment.

The temperature was 104 F, the pulse rate 120 and the respiratory rate 28 per minute. The patient was acutely ill. She could only partially open her mouth and talking was

Fig 3 (case 2) —Results of blood studies in case of peritonsillar abscess

extremely painful. The skin was warm and moist. The mucous membranes were of good color and no cyanosis or jaundice was noticed. The right side of the face over the region of the mandible was swollen, rather indurated and quite tender. The right tonsillar gland was quite large, firm and tender. Above the tonsil on the right was a large, fluctuant tender swelling which displaced the uvula to the opposite side of the throat. The heart was normal and the lungs were clear to percussion and auscultation. The liver and spleen were not palpable. The remainder of the physical examination showed no abnormalities. The patient weighed 51 Kg (122 pounds).

Laboratory examinations revealed the following: Urine specific gravity 1.030, sugar negative, albumin 2 plus acetone and urobilin positive, sediment normal. Blood: Red blood cells 4,250,000, hemoglobin 70 per cent, white blood cells 20,400. Differential count: juvenile neutrophils 15 per cent, adult polymorphonuclear leukocytes 70 per cent, lymphocytes 13 per cent, monocytes 2 per cent. There was no sickling of the red blood cells immediately or at the end of twenty-four hours. The platelets were normal and no parasites were seen. Slight anisocytosis was present. The Wassermann reaction was negative. A throat culture showed 50 per cent beta hemolytic streptococci. The blood culture was sterile.

The diagnosis was peritonsillar abscess and it was decided to try the effect of sulfanilamide medication before incising the area. Because of the patient's inability to swallow she was given 41 Gm of sulfanilamide subcutaneously in 450 cc of physiologic solution of sodium chloride. The following morning the blood concentration of the drug was found to be 98 mg per hundred cubic centimeters. The patient's condition was not improved, so that the abscess was opened and a large quantity of pus was removed. After this she received 0.6 Gm of sulfanilamide every four hours by mouth for four doses.

Thirty-six hours after the sulfanilamide had been administered subcutaneously the patient was found to be irrational and very drowsy. The mucous membranes were pale and definitely icteric. Examination of the blood confirmed the opinion that the patient had a severe hemolytic anemia. The hemoglobin had dropped to 39 per cent with an erythrocyte count of 2,250,000. The white cells now numbered 30,000, of which 9 per cent were myelocytes, 18 per cent juvenile neutrophils, 65 per cent adult polymorphonuclears, 5 per cent lymphocytes and 3 per cent monocytes. In the blood smear an occasional myeloblast was found and numerous nucleated red blood cells were present. The platelets were abundant. The reticulocyte count was 2 per cent. The clotting time and fragility of the red blood cells were normal and the Donath Landsteiner test was negative. Within the next twelve hours, before a transfusion was given, the hemoglobin dropped to 18 per cent and the red blood cells to 2,000,000. The icterus index of the blood was 20 and the blood bilirubin was 2.0 mg per hundred cubic centimeters. Large amounts of bile and urobilin were present in the urine but no hemoglobin was detected. The blood para-aminobenzenesulfonamide concentration was now 66 mg per hundred cubic centimeters. A bromsulfalein test of liver function showed 28 per cent retention of the dye thirty minutes after the injection of 5 mg per kilogram of body weight.

During the next twenty-four hours the patient was given two transfusions of citrated blood of 500 cc each. The following day she was still listless and weak but was quite oriented. The liver was felt just below the costal margin but the spleen was not palpable. The hemoglobin had risen to 48 per cent. The white cell count was 14,200 and large numbers of immature cells were still present in the smear. Numerous nucleated red blood cells were seen and the reticulocyte count was 3.6 per cent.

The patient continued to improve. The weakness and jaundice disappeared and the throat healed rapidly. Nine days after the development of the hemolytic crisis the hemoglobin had risen to 55 per cent with a red blood cell count of 2,580,000. The white cell count was 8,900, the smear showed many immature white cells and there was marked evidence of red blood cell regeneration as evidenced by a reticulocyte count of 12.5 per cent. All the bromsulfalein was excreted within thirty minutes after injection. The results of the frequent blood examinations made during the recovery period are shown in figure 3.

The sulfanilamide determinations of the blood were made by the method of Marshall, Emerson and Cutting through the courtesy of Dr. Marshall and Miss Margaret Strauss.

CASE 3—A white baby girl aged 10 months, was admitted to the Harriet Lane Home of the Johns Hopkins Hospital April 6, 1937 because of fever, irritability and stiff neck for three days. The family history and the past history were non-contributory. The baby had always been healthy, she had a normal birth at full term and had developed normally.

Four days before admission the mother noticed that the child was less lively than usual. Three days before she had become restless and feverish and had vomited all her feedings. Two days previously a stiff neck developed, she refused nourishment and cried out whenever she was touched or moved. On the day before admission she seemed better but kept her head drawn back. Finally her temperature rose again, her right eye became crossed and she was brought to the hospital.

The baby was acutely ill on examination. She was rather fat and flabby with well marked opisthotonos. The child lay quiet but cried out whenever she was disturbed. The temperature was 40.2 C (104.4 F), the pulse rate 170 and respirations were rapid and shallow. No skin eruption or jaundice was

5 Marshall E. K. Jr., Emerson Kendall Jr. and Cutting W. C. Para-Aminobenzenesulfonamide. J. A. M. A. 108: 953 (March 20) 1937.
6 This case is reported through the courtesy of Dr. Edward A. Park.

noted. The skin was warm and a little pale. The mucous membranes were of fair color. The anterior fontanel was bulging and tense, the neck was rigid and the reflexes were jerky. Brink's, Kernig's and Brudzinski's signs were not present. The eyes showed convergent internal strabismus, more marked on the right. The fundi were normal. There was congestion of the ear drums but no bulging and the throat was normal in appearance. The heart, lungs and abdomen were normal. The baby weighed 9.5 Kg.

Laboratory examinations revealed the following: Urine orange, acid, no albumin or sugar; sediment negative, urobilin not present in abnormal amounts. Blood: On admission hemoglobin 65 per cent, red blood cells 4,120,000, white blood cells 14,300 with 42 per cent adult and 18 per cent immature polymorphonuclears, 32 per cent lymphocytes and 8 per cent monocytes. The smear showed slight anisocytosis and polychromatophilia. The platelets appeared normal.

Lumbar puncture was done on admission, 20 cc of cloudy fluid was removed under rather low pressure. The Pandy test was strongly positive, sugar was negative. The cells numbered 11,400, almost all of which were polymorphonuclear cells. The smear was loaded with gram-negative diplococci which were mainly extracellular. Culture of both the blood and the spinal fluid showed meningococci.

On the basis of the clinical picture and laboratory examinations a diagnosis of meningococcal meningitis was made and the child was started on treatment with sulfanilamide. On the first day she was given a subcutaneous infusion containing 1.42 Gm, followed later by another 1.5 Gm by the same route. For the next three days she was given a daily dose of 1.6 Gm subcutaneously and from 0.2 to 0.3 Gm intraspinally making a total of approximately 2 Gm daily, or 0.2 Gm per kilogram of body weight. Lumbar or cisternal punctures were done twice every twenty-four hours and as much fluid as possible was drained off before sulfanilamide was administered.

The child remained critically ill for forty-eight hours with marked cyanosis, rapid pulse and shallow respiration but during the third day her condition began to improve and by the fifth day she was well enough to take almost all her food and fluid by mouth and with it a daily dose of 2.4 Gm of powdered sulfanilamide. Her neck was no longer stiff at that time. Coincident with the clinical improvement, the spinal fluid began to clear with a steady decrease in the number of cells to only 350 on the fifth day. It was noted that in the smear most of the organisms were extracellular on admission but eight hours after treatment was started most of them were intracellular. Cultures, positive for meningococci at the first two punctures, became sterile after the first day.

On the seventh day her temperature which had fallen to 38.2 C (100.8 F), rose again to 40 (104 F) and the house officer, Dr. E. DeSoto, was impressed by the marked discrepancy between the temperature chart and the patient's satisfactory condition, negative physical examination and normal spinal fluid. He noted an extreme pallor of the skin and mucous membranes and promptly made a complete blood examination, which showed a fall in hemoglobin from 65 per cent to 40 per cent and a drop in the number of erythrocytes from 4,120,000 to 2,020,000 and a rise in white blood cells to 32,400. In the smear an abundance of immature polymorphonuclear leukocytes, nucleated red blood cells and reticulocytes was noted. The platelets appeared normal. The differential count revealed adult polymorphonuclears 35 per cent, immature polymorphonuclears 36 per cent (including 5 per cent juvenile cells and 4 per cent myelocytes), 25 per cent lymphocytes, 1 per cent monocytes, 10 per cent nucleated red blood cells and 12 per cent reticulocytes.

A diagnosis of acute hemolytic anemia was made despite the absence of icterus or increased urobilinuria, and an increased urobilin excretion in the stools was found by Dr. Hugh Josephs to confirm this. The administration of sulfanilamide was stopped and the child was given transfusions of 90 cc and 50 cc of citrated blood on the seventh and eighth days, and on the ninth day of her illness the temperature came down to normal. At this point the child was eating well but seemed pale and weak. Blood counts on the tenth day showed hemoglobin 70 per cent, red blood cells 3,690,000, white blood cells 11,200 with adult polymorphonuclears 36 per cent, stab forms 46 per cent (including 2 per cent juvenile cells), 12 per cent

lymphocytes, 6 per cent monocytes, 0.5 per cent nucleated red blood cells and 6 per cent reticulocytes. Since then the child has continued to improve steadily.

COMMENT

Three instances of severe hemolytic anemia appeared during the course of infections which were treated with large doses of sulfanilamide (para-aminobenzenesulfonamide). That the drug was directly responsible for the development of these anemias cannot be proved conclusively, but in view of the facts it is certainly a reasonable assumption.

Other conditions that produce an acute anemia of this type have been fairly well ruled out. These patients were not suffering from hemolytic jaundice, sickle cell anemia or paroxysmal hemoglobinuria. The clinical picture shows a striking resemblance to the cases of Lederer's anemia that were reviewed by O'Donoghue

Fig. 4 (case 2)—Blood smear showing several immature myeloid cells, large platelets and one nucleated red cell.

and Witts.⁷ Only one instance of this type of acute hemolytic crisis could be found in a search of the records of this hospital during recent years, and none have been observed during the course of a streptococcal sore throat.

When the patients were well enough for discharge, an attempt was made to reproduce the clinical picture in mild degree by the administration of a small dose of the drug. Patient 1 was given 0.9 Gm of sulfanilamide orally, and the blood concentration of sulfanilamide rose to 10 mg per hundred cubic centimeters after five hours, while patient 2 received 0.5 Gm orally with a blood level of 0.8 mg per hundred cubic centimeters after four hours. Careful blood studies were made just before the dose and four, fifteen, thirty, fifty and 120 hours afterward while the excretion of urobilin was carefully followed in the urine and stool. At each examination of the blood the hematocrit and icterus index were determined, the reticulocytes and

⁷ O'Donoghue, R. J. I., and Witts, I. J. *Glasg. Hosp. Rep.* 82: 440 (Oct.) 1932.

total leukocytes were counted and stained smears were examined for changes in the red blood cells and platelets. No significant changes were noted in the blood, and the patients themselves had no symptoms, with the exception of slight nausea in one who knew what was being done. Quantitative determinations of urobilin excretion in the stool showed a definite rise from a daily average figure of from 50 mg to 400 mg in case 2. This is rather difficult to evaluate, as there was considerable variation during the control period, and there was no evidence of increased hemolysis in the blood examinations. It was not possible to keep these patients in the hospital for further study, nor was it felt justifiable to administer a much larger test dose.

With the assistance of Dr. Edmund L. Keeney, skin tests were performed on each of these patients, a mixture of sulfanilamide and normal human serum made up twenty-four hours before being used as the testing substance and equivalent mixtures of sulfanilamide with saline solution and serum with saline solution as controls. Each skin test dose of 0.2 cc given intradermally contained 0.05 cc of serum mixed with 0.15 cc of a 1 per cent solution and was therefore equivalent to 3 mg of the drug. The patients were observed carefully for an hour and were examined again at twelve and twenty-four hours but no positive reactions were obtained.

Sulfanilamide has been given to patients in similar amounts many times without any effect on the blood picture. Two of our patients were given an additional small dose of sulfanilamide without any reappearance of the peculiar blood picture. These facts lead one to believe that this is not a question of toxicity from overdosage or the type of drug idiosyncrasy that occurs in some cases after aminopyrine. The resemblance of these hemolytic anemias to the hemolytic crises produced by the use of phenylhydrazine is quite striking. It is possible that these individuals produce from the sulfanilamide a small amount of a toxic product having an action like phenylhydrazine or produce such a substance much more rapidly than the average patient.

It is essential to emphasize two important points in connection with these cases. First, whenever patients are being given large doses of the drug the blood picture must be carefully followed, especial attention being paid to the evidences of red blood cell destruction and regeneration such as reticulocytosis, the appearance of nucleated red blood cells and the presence of bile and urobilin in the urine, feces or blood. Secondly, the anemia was promptly improved and the symptoms disappeared after transfusions of citrated blood in these cases. Thus the treatment of this type of anemia is much more satisfactory than that of the aplastic type, which sometimes develops after the use of arsenical drugs.⁸

SUMMARY

Three cases of acute hemolytic anemia developed during the course of infections being treated with large doses of sulfanilamide.

⁸ Since this report was submitted two additional cases of hemolytic anemia occurring during the treatment of infections with sulfanilamide have been observed.

The blood of patients receiving large doses of the drug should be followed carefully for evidences of red blood cell destruction and regeneration.

In the three instances the patient recovered after the medication was stopped and transfusions of citrated blood were given.

Two of the patients were given a small dose of the drug after recovery with no change in the blood picture.

710 North Washington Street

TRAUMATIC CHYLOTHORAX FROM RUPTURED THORACIC DUCT

TREATED BY INTRAVENOUS INJECTION OF THE ASPIRATED CHYLE

E. HERBERT BAUERSFELD, M.D.
WASHINGTON, D. C.

Chylous effusion in the chest from traumatic injury to the thoracic duct is a rare condition. Although Zesas¹ in 1912 stated that the first case was reported by Bartolet in 1633, the first authentic case was reported

Fig. 1—Massive right pleural effusion Sept. 17, 1936, the day preceding the first thoracentesis.

Fig. 2—Complete right artificial pneumothorax, October 1.

by Quincke² in 1875. In his article Zesas also reviewed eighteen reported cases of traumatic chylothorax, dating from Quincke's case. MacNab and Scarlett³ in 1932, adding their own case, found fifteen cases reported since the collection of Zesas. This made a total of thirty-four published reports of authentic cases. In 1933 Mouchet⁴ found forty-three reported cases, but this included some cases which Zesas had discarded because of insufficient data. Since Mouchet's article there have been five cases reported.⁵ The majority have been published in the French and German literature. In this country only six cases

have been reported by Watts⁶ in 1921, Andrews⁷ in 1929, MacNab and Scarlett in 1932, Heppner⁸ in 1934, Scott⁹ in 1934 and Lillie and Fox¹⁰ in 1935

GENERAL DISCUSSION OF THE CONDITION

Anatomy and Physiology—The duct starts as a dilated portion, the cisterna chyli over the body of the second lumbar vertebra, and there receives all the lymphatic drainage and most of the fat that is absorbed from the intestine. It is to the right of and behind the aorta, it then passes through the diaphragm at the aortic hiatus into the posterior mediastinum between the aorta and the azygos vein just over the vertebral column. Opposite the fifth thoracic vertebra it inclines toward the left, enters the superior mediastinal cavity and ascends behind the aortic arch into the neck, emptying into the angle of the junction of the left subclavian vein with the left internal jugular vein. The chyle passes through the duct at the rate of from 130 to 195 cc an hour.

Etiology—As suggested by MacNab and Scarlett, the traumatic etiologic factors may be classified in this manner:

A External violence

- 1 Closed trauma—no external wounds or fractures
- 2 Trauma with fractured ribs, clavicles or vertebrae
- 3 Gunshot wounds
- 4 Stab wounds

B Operative wounds

- 1 Complete severance of the duct
- 2 Section of one or more terminals

Symptoms—There is characteristically a lapse of from four to six days between injury of the duct and onset of the symptoms, although in the case reported by Heppner there was an interval of nine weeks. The symptoms are progressive dyspnea, cyanosis, shock and signs of pleural effusion. On aspiration a noncoagulable, milky fluid is obtained which contains fat globules, has a specific gravity greater than 1.012 and is alkaline in reaction. Since normally from 130 to 195 cc of chyle passes through the duct hourly, the effusion rapidly reaccumulates and requires repeated aspiration. Along with this is a progressive and rapid emaciation and exhaustion of the patient as the result of loss of chyle. In the majority of cases the effusion is located in the right pleural cavity. This is explained by the fact that the duct is most frequently injured in its lower two thirds, between the tenth and the fifth thoracic vertebra and in this location it lies to the right of the midline. Of the twenty-eight cases reviewed by MacNab and Scarlett, the effusion occurred in fifteen on the right side and in eight on the left side, in five it was bilateral.

Prognosis—The prognosis is grave, the mortality averaging about 50 per cent in the reported cases. In Mouchet's series of forty-three cases it was 41 per cent, while in that of MacNab and Scarlett there were sixteen fatalities in thirty cases. Of the six cases heretofore reported in this country, recovery has occurred in two.

Treatment—The treatment has been a most difficult problem, as the chyle is essential for life, if the degree of leakage from the duct is too great, death from depletion ensues in about three weeks. Numerous surgical procedures have been tried, but at this time the

consensus is against surgical intervention. In an endeavor to aid healing of the duct and to prevent the loss of chyle, two procedures have been tried without conspicuous success: first, an attempt to decrease the formation of chyle by a fat-free diet, or rectal feedings with nothing by mouth, second, to perform a thoracotomy to eliminate the negative pressure, which may act as a suction. Heppner treated his patient by feeding him the aspirated chyle, but this gave only temporary results and the patient succumbed. Intravenous administration of the aspirated chyle has been resorted to but once in the reported cases. Oeken⁸ in 1908 attempted this procedure, but the patient did not recover.

REPORT OF CASE

R. L., a white man, aged 22, was brought to the Central Dispensary and Emergency Hospital about 4 a. m. Sept. 11, 1936, following an automobile accident.⁶ He had been unconscious for a short period after the accident but was conscious on reaching the hospital. He had a laceration of the scalp and complained of pain in the lower part of the abdomen and lumbar region. He was admitted to the hospital with the tentative diagnosis of a fractured skull and internal injuries.

The past history revealed a minor football injury of the shoulder in 1935 with a residual neuritis. There was no history of previous chest injuries or diseases of the lungs and no illnesses other than the usual childhood diseases.

For the first twenty-four hours after admission there was projectile vomiting. This subsided, and the possibility of a fractured skull was eliminated by x-ray and clinical examinations. On the 13th, two days after admission, there was a slight cough, which was treated symptomatically. On the 15th, four days after admission, the patient complained of a sharp pain in the chest just to the right of the sternum. This increased in severity and the cough became worse. On the 16th he was about the same with no relief from the lumbar pain, which now was located at about the midline just below the twelfth rib. On the 17th, breathing was labored, there was some cyanosis and coldness of the extremities, although the patient stated that he felt hot. The pulse was of fair quality. On the 18th, eight days after admission, the symptoms were still more pronounced with respirations more labored, skin cold and clammy, and a moderate degree of cyanosis. The pulse was weak and thready. The blood pressure was 110 systolic, 90 diastolic, and the patient was expectorating a small amount of frothy sputum. Examination of the chest revealed a massive right pleural effusion with a marked mediastinal shift to the left.

Immediate aspiration was done and 2,400 cc of a rose colored fluid of the consistency of milk was withdrawn. This did not empty the pleural cavity, but the procedure was stopped on account of the onset of a cough. Following this thoracentesis the patient immediately improved. The next day aspiration was repeated as the mediastinum had again shifted, and 3,100 cc of fluid was withdrawn. No aspiration was done on the 20th, but thereafter it was necessary to aspirate from 1,500 to 3,200 cc daily to keep the patient free from respiratory embarrassment. After the first aspiration the fluid gradually became a creamy color, and at no time did it coagulate.

On this regimen the patient progressively lost weight and strength. The pulse was weak, thready and sometimes not obtainable. The blood pressure rather constantly remained 90/80. There was no decrease in the rate of accumulation of the fluid.

It was thought possible that the daily aspirations by increasing the degree of negativity in the intrapleural pressure might be favoring the reaccumulation. To eliminate this factor it was decided to inject 30 cc of air for each 50 cc of fluid withdrawn. Beginning September 24 this was done at each aspiration for three days without demonstrable effect. The patient continued to lose ground and was securing less and less mechanical relief from the aspirations.

September 27 another procedure was tried, the thought of which had not occurred to us until that date. The chest was

9 Dr. John Lyons gave me the privilege of reporting this case.

again tapped, but the tubing was hooked up with a direct transfusion set, a 20 cc syringe being used and the fluid was reinjected into the right median basilic vein until 1,000 cc was administered. After this 2,200 cc was withdrawn and discarded. No reaction followed and in an hour or two there was marked clinical improvement. The pulse was full and regular, the blood pressure was 114/60, the color was improved and the patient stated that he was feeling fine. That night he slept well and the next day he was much improved. There did not seem to be much fluid in the chest, but it was again tapped, and the direct transfusion set was again used, however only a little over 200 cc could be obtained from the chest. This was injected into the vein. From this point on the patient improved steadily and rapidly. The circulation returned to normal, the blood pressure rose to 125/70 and there was a striking gain in weight. October 23 he was discharged from the hospital. Although he had been using blow bottles for ten days prior to discharge, he still had at that time a moderate degree of pneumothorax.

During the course of his illness, 22,275 cc of chyle had been removed from the chest, 1,200 cc of which was injected into the vein. In addition to the treatment previously mentioned he received such supportive measures as intravenous dextrose and a high caloric diet. At one time a fat free diet was attempted, but this the patient refused to eat.

It should be mentioned that the fever was at no time remarkable, its maximum being 101 F. Also the x-ray examination of the chest revealed no fractures. Laboratory examination of the aspirated fluid showed (1) no growth on repeated cultures, (2) specific gravity 1.012, (3) alkaline reaction, (4) numerous fat globules after extraction with ether, (5) numerous cells—lymphocytes and occasional red blood cells, and (6) no coagulation.

This case is interesting in that it fits so well into the picture of traumatic rupture of the thoracic duct with resultant right chylothorax. It is the second recorded case in which the aspirated chyle was injected intravenously and the first case so treated in which recovery occurred. It is by all odds most probable that the sealing of the tear in the duct and the intravenous injections were coincidental and unrelated. However, it has been quite definitely shown that the intravenous injection of sterile chyle has no harmful effect, and there is reason to believe that resorted to early it would serve a most helpful purpose in overcoming the very serious loss of ingested fats. It was only after the patient had been under treatment sixteen days that this procedure occurred to us, and not until after the patient had been discharged from the hospital that on searching the literature we learned that it had been used before. In view of these facts it is perhaps not untimely that this method of supportive treatment in traumatic rupture of the thoracic duct should be emphasized.

He Also Serves Who Waits—In these days when science is clearly in the saddle and when our knowledge of disease is consequently advancing at a breathless pace, we are apt to forget that not all can ride and that he also serves who waits and who applies what the horseman discovers. In some of our schools so great an emphasis has come to be laid on the science courses with the patient long hidden from sight, that the better students, under the influence of teachers who have never had clinical experience naturally come to feel that somehow the practice of medicine among the people is an inferior calling compared to the secluded life of an investigator, and that to justify themselves in the eyes of the faculty they must manage to 'do a piece of research'—Cushing Harvey. *Consecratio Medici and Other Papers* Boston, Little Brown & Co., 1928

ARTIFICIAL FEVER THERAPY OF GONORRHEA IN THE MALE

A COMPARATIVE STUDY

DENVER

Our purpose in this report is to present a series of clinical studies of gonorrhea in the male treated with artificial fever therapy compared with a similar series of cases treated by more time-honored methods. If a therapeutic measure is to be properly evaluated, the terms of clinical experimentation should approximate the more exact methods of the laboratory. Fever therapy should be no exception to this generalization. Because of the fundamental work of Warren, Carpenter, Boak and their associates¹ together with numerous more purely clinical studies,² we felt justified in setting up a clinical experiment of this type. Our object was to study one group of young men whom we treated with artificial fever, at the same time and under as nearly identical conditions as possible we studied a second group of young men whom we treated with irrigations, injections and massages.

We determined that, from our point of view, there were two questions of significance in this study: (1) Would fever therapy accomplish more cured cases than any other type of therapeutic measure so far available and (2) would fever therapy reduce the duration of the infection?

MATERIAL

The clinical material available for this study consisted of eighty-seven young men, all except one of whom were white. All were between the ages of 18 and 49. All of these men were placed in isolation, under constant observation during the period of study. They were kept at rest during the period of treatment without reference to the type of therapy used. All patients were volunteers for the study and cooperated well throughout the period of observation and follow up. Each patient fully understood in which group he was placed and the reasons for his classification. Only one patient objected to continuing fever therapy and

Dr. Bowman died April 18, 1937.

elected to rely on the more standard measures. This young man developed a most severe arthritis and is still in a wheel chair after six months. Doubtless he has served as an example to other possible timid souls in the group who might have otherwise objected to the discomfort of fever therapy. Of the group of eighty-seven patients, forty-three were treated with fever therapy, forty-four were treated by the usual means

EQUIPMENT

Through the courtesy of Dr. Walter M. Simpson and Mr. C. F. Kettering, two Kettering hypertherms were provided for this and certain other studies. This apparatus has been described elsewhere³ and therefore needs no further description at this time. This equipment has in our hands proved to be a thoroughly satisfactory modality for the induction, maintenance and control of fever.

METHOD

Patients assisting in this study were, after examination, classified into the following series:

1. Acute gonorrhea, urethritis of less than ninety days' duration, without demonstrable complication such as prostatitis or the like. No effort was made to differentiate further between anterior and posterior urethritis.

TABLE 1—Acute Gonorrhea

	Fever Treated Group	Control Group
Number of patient	11	11
Time treated (days)	24	81
Percentage cured	72.7	72.7
Residuals (prostatitis and other complications)	0	3
Average amount of effective fever required (hours)	21 plus	

2. Acute prostatitis and complications, urethritis plus prostatitis, seminal vesiculitis and often epididymitis, all of less than ninety days' duration.

3. Chronic prostatitis and complications, morning urethral discharge or more, with clinical prostatitis and often seminal vesiculitis, epididymitis or the like of more than ninety days' duration.

All cases showed typical micro-organisms in Gram-stained smears. In actual practice we selected the cases for fever therapy and then selected control cases to parallel the fever-treated group.

Persons given fever therapy were treated for five hour periods at temperatures of 106.6-107 F every third day. Treatment was continued in each case until at least one treatment was given after the patient was clinically and bacteriologically well.

Proof of "cure" in gonorrhea has long been a bone of professional and lay contention. During this study we found that we could be reasonably sure of our results if the patient responded clinically after two or three treatments and then was given from one to two additional "safety first" treatments. Following clinical "cure" these patients were then placed on labor details and worked at hard manual labor under supervision. They continued to live in an isolated, protected environment for a period of thirty days. Each patient was examined at least once daily, and at least three prostatic smears were studied microscopically each week during the probationary period. If the patient remained clinically well and bacteriologically negative in the sense of

presenting normal prostatic smears for this time, he was then returned to a normal work status, reporting to a physician for examination every week. This last has proved effective in only about one third of the cases, since we were necessarily forced to relinquish our previous complete control of the patient when he returned to his work. The patients and their physicians have cooperated well, however, so that all the "cures" reported here are clinically and bacteriologically nega-

TABLE 2—Acute Prostatitis and Complications

	Fever Treated Group	Control Group
Number of patients	14	14
Time treated (days)	22	84
Percentage cured	85.8	71.4
Average amount of effective fever required (hours)	18 plus	

tive entities of at least five months' duration. When it is realized that the group under consideration is a laboring group almost exclusively, the term "cure" as used here would appear to be, for all practical purposes, satisfactory. Many of these men have reported alcoholic excesses without evidence of recurrence.

RESULTS

SERIES 1—Acute Gonorrhea—The data from this series are presented in table 1. In this series it will be noted that the number of cures in each group was the same, 72.7 per cent, but the fever-treated cases showed no residuals (such as chronic prostatitis) and accomplished the result in approximately one-third the time required in the control group. The control group were under treatment a total of 594 days longer than were the fever-treated group.

SERIES 2—Acute Prostatitis and Complications—The data from this series are presented in table 2. In this table it will be noted that the number of cures in the fever-treated group is significantly greater than is the case of the control group. The time required for the treatment of the fever-treated group was approximately one-fourth that necessary in the control group. It is of interest to note that, in the fever-treated group, cases of acute prostatitis with urinary retention and severe pain were uniformly rendered asymptomatic in one treatment.

SERIES 3—Chronic Prostatitis and Complications—The data from this series are presented in table 3.

TABLE 3—Chronic Prostatitis and Complications

	Fever Treated Group	Control Group
Number of patients	18	19
Time treated (days)	28	105
Percentage cured	88.8	31.5
Average amount of effective fever required (hours)	22 plus	

This series represents the most resistant type of case encountered. In the control group it will be noted that we felt justified in classing less than one third of our cases as cured, whereas the fever-treated group showed definite cures in all but two cases. These last two cases were twelve and fifteen years, respectively, in duration. The time required for treatment was approximately four times as long in the control group as in the fever-treated group.

COMMENT

This study has been carried on over a period of one year, during which time complete control has been maintained over all patients, both fever-treated and control groups. The average age of the patients in the entire study was 27 years, although several were above the age of 40. We have observed increased technical difficulties in treating with fever patients older than 40 years. Although no statistical study was made on the point in this small series, we have gained the impression that relatively few patients above the age of 40 tolerate fever therapy for gonorrhea safely. No untoward effect was noted from fever therapy in this entire study.

Study of the cases in which failure to accomplish a "cure" was noted indicates that, in each case in which fever therapy was used, inadequate treatment was given. This was, with one exception, due to poor judgment on our part. The one exception noted was a white man of 49 who had an active duodenal ulcer as a complicating factor. Because he tolerated fever poorly he was given only seven hours of effective fever, after which all urethral discharge ceased and he became asymptomatic. Oddly enough, his ulcer symptoms became less and he gained 28 pounds (13 Kg.) during a forty day probationary period. This case is classified as "improved."

Two fever-treated patients developed gonorrheal ophthalmia after the first treatment, apparently because of carelessness on the part of each patient. In each case this complication cleared entirely when the second treatment was given.

In no case treated with fever therapy was the final bacteriologic examination positive, in seven cases in the control group the prostatic smears occasionally showed typical micro-organisms even after the symptomatology was negative. All such cases are classified as improved rather than cured.

This study was undertaken not with the idea of criticizing any form of therapy but in order that we might evaluate fever therapy and chemotherapy in our own hands. Other clinics have reported quicker results with potassium permanganate irrigations and silver salt instillations than we have obtained, still others have reported greater periods of time as a necessary requirement. We know of no work, however, in which the investigators have been so fortunate as have we in having complete control of all our patients throughout the entire series. The United States Army⁴ reports a loss of approximately fifty days' time from duty in the average case of gonorrhea. This is approximately twice that which we have observed in the fever-treated cases but less than we found in our control cases. The army figures, however, do not show recurrences with rehospitalizations, so that the total loss of time in the average individual case of gonorrhea is higher than the reported figure of fifty days. Brunet and Seltzer⁵ found that the average duration of treatment for the complicated cases was 148 days and for the uncomplicated cases eighty-nine days. The last-mentioned figures are not remarkably different from the figures in our control group. The chemotherapy utilized by these workers was essentially that which we applied in our control group. It is also of interest that these workers report the discharge of only 32.5 per cent of all their

cases as cured, which is less than the percentage of cures which we obtained in our control group. Although our series of cases is not large it would appear to be representative and the data valid.

CONCLUSIONS

- 1 Fever therapy accomplishes more cures in gonorrhea in the male than does chemotherapy.
- 2 Fever therapy greatly reduces the duration of gonorrheal infection in the male.

PHENOBARBITAL CONTRAINDICATED
IN PARKINSONISM

EUGENE ZISKIND, M.D.

AND

ESTHER SOMERFELD ZISKIND, M.D.

LOS ANGELES

By error in December 1935 a patient suffering with chronic encephalitic parkinsonism was given phenobarbital 1½ grains (0.1 Gm.) three times a day instead of his usual scopolamine hydrobromide therapy. Within four days he became bedridden with rigidity so marked that the body could be moved as if made of one block. This extreme rigidity disappeared very rapidly when the phenobarbital was discontinued, the condition returning to its previous state. Recently we saw another patient with the same illness who, as a result of phenobarbital therapy, had a marked aggravation of her rigidity, which receded on removal of the drug. In addition, we have administered this drug in three other cases of parkinsonism for the purpose of observing the effect on rigidity. The following reports demonstrate the inadvisability of using phenobarbital in patients with Parkinson's disease.

REPORT OF CASES

CASE 1—*Ambulatory patient with parkinsonian rigidity of seven years' duration due to lethargic encephalitis. Profound increase of rigidity resulted in confinement to bed after administration of phenobarbital. Return to previous state after this therapy stopped.*

G. Y., a man, aged 49, presented himself at the Good Hope Clinic in 1932 with a tremor of the right hand, dragging of the right foot and pain in the right shoulder and right upper quadrant of the abdomen, all of four years' duration. The tremor and dragging of the leg were progressive, as was the abdominal pain, which was not related to the intake of food and was described as feeling as if a brick were there. The remainder of the systemic history was essentially negative. There was a history of influenza in 1918, when the patient was confined to bed for six weeks and was lethargic most of the time. He did not recover strength for the ensuing three or four months and after that suffered with insomnia and impaired vision for six months.

The past history included also pertussis and measles in childhood, an infection of the right index finger in 1911 and tonsillectomy in 1920.

The general physical examination revealed no pertinent abnormalities. The neurologic examination showed masked facies, flexion posture with plastic rigidity of the right arm, dragging of the right foot, loss of associated automatic movements in the right arm in walking, coarse tremor of the right hand and arm particularly marked when at rest, slight right facial weakness of the central type, more marked on emotional expression, paralysis of ocular convergence, and hyperactive deep reflexes. The plantar reflexes and the remainder of the neurologic manifestations were within normal limits.

The blood count was normal and the blood Wassermann reaction was negative. On one occasion 1 per cent sugar was

⁴ Annual Report of the Surgeon General U. S. Army 1935 Washington: D. C. United States Government Printing Office 1935.

⁵ Brunet, W. M. and Seltzer, Sam. *The Treatment of Gonorrhea in the Male. A Study of 600 Cases of Gonorrhea Treated with Irrigations of Potassium Permanganate and Injections of Silver Proteinate.* Am. J. Syph. Gonorr. & Ven. Dis. 20: 492 (Sept.) 1936.

discovered in the urine, but later urine tests were all negative and the blood sugar was 122 mg per hundred cubic centimeters. Roentgenograms of the chest, gallbladder, gastro-intestinal tract and genito-urinary tract were negative.

The diagnosis was parkinsonism due to chronic encephalitis. The patient was placed on scopolamine hydrobromide therapy. During the course of the next three years considerable rigidity in all extremities and bilateral tremor developed. Dec 4, 1935, he was given phenobarbital $1\frac{1}{2}$ grains three times a day by mistake in place of scopolamine hydrobromide. Five days later this previously ambulatory patient became bedridden and when seen December 12 presented an extreme degree of rigidity, so that the entire body could be moved as if in one piece. After phenobarbital was discontinued, the extreme rigidity disappeared and the condition returned to the previous state within a few days. At the present time he seems to be none the worse for the experience.

CASE 2—Woman, aged 58 with parkinsonism of four years duration plus hypertension and a mild degree of arteriosclerosis. Parathyroidectomy one and one-half years before with aggravation of parkinsonian symptoms. Phenobarbital therapy produced a bedridden condition because rigidity increased. Disappearance of aggravated symptoms when phenobarbital was discontinued. Reproduction and disappearance of same symptoms when phenobarbital was again consecutively administered and discontinued.

We first saw the patient at the Cedars of Lebanon Hospital, Nov. 21, 1936, and were informed that when she had presented herself at the outpatient department nine days previously the diagnosis of Parkinson's syndrome was made and she was given prescriptions containing potassium iodide, tincture of stramonium and phenobarbital, respectively. The phenobarbital was administered in doses of $1\frac{1}{2}$ grains three times a day. The patient's symptoms had become acutely aggravated so that she could not leave her bed, and she was therefore admitted to the hospital November 16. Here she received tincture of stramonium plus phenobarbital 1 gram (0.065 Gm.) at night until seen by us.

At our examination the presenting complaints included tremor of the lips, hands, arms and legs and weakness of four years' duration. The onset was insidious after the death of a son four years before. At first the tremor appeared in the feet, later it involved the hands, the right side being more affected than the left. The tremor increased on emotional tension and disappeared during sleep and also with motion. The symptoms were progressive, becoming definitely increased at the time the husband died one year after the onset. Eighteen months before admission the patient had one or two parathyroid glands removed in an attempt to cure the symptoms. The parkinsonism, however, became more marked. At that time the blood pressure was known to be 180 systolic, 100 diastolic. However the patient was able to work, and nine months before admission she took a bus ride from Chicago to Los Angeles. She presented herself at the clinic because of progressive disability but was apparently able to get around and care for her wants. She had lost 45 pounds (20 Kg.) in the last eighteen months. Otherwise no pertinent symptoms other than constipation and free perspiration were noted on systemic inquiry. Both the patient's mother and son had died of carcinoma. Appendectomy and hernioplasty had been performed fifteen years previously. There was no history of influenza or encephalitis. The patient had passed the menopause.

On physical examination the temperature was 96 F, pulse 60, respiration rate 20, blood pressure 190 systolic, 124 diastolic and weight 123 pounds (56 Kg.). The teeth were absent, the heart was enlarged to the left beyond the nipple line in the fourth intercostal space, and there was sclerosis of the peripheral vessels. There was an operative scar over the thyroid and also on the abdomen. The temperature had been 98.2 F on admission five days earlier, but had gradually fallen each day until it was 96 F at this examination.

Neurologically the patient presented the familiar picture of parkinsonism with an extreme degree of rigidity. She was confined to bed, with inability to turn herself from side to side or to sit up unaided. The spine was flexed anteriorly, the neck and head were held rigid, and the four extremities were sharply flexed. The pin rolling posture of the hands was classic. There were characteristic masking of the face, tremor of the tongue and jaws, and definite dysarthria. The patient showed some degree of emotional instability in that she laughed and

cried spasmodically. Nystagmus was recorded in an earlier examination but was not present at this time. Weakness was particularly marked, the dynamometer registering 25 for the right handgrip and 50 for the left. There was a coarse tremor of both hands and legs, being more marked at rest and tending to disappear in motion. Cogwheel rigidity of the extremities was demonstrated both on extension and on flexion. Although able to walk previous to coming to the hospital, the patient at this time could not stand unassisted. The remainder of the neurologic examination was negative. A diagnosis was made of Parkinson's syndrome, probably on an arteriosclerotic basis. The acute exacerbation of parkinsonian rigidity was attributed to phenobarbital in view of our past experience with this drug.

The phenobarbital was discontinued and the patient became progressively better, so that she was able to walk and help herself in and out of bed, as she had done previous to coming to the outpatient department. The temperature returned to normal. November 29, the patient was walking unaided. On that day scopolamine hydrobromide $\frac{1}{100}$ grain twice a day was prescribed and the tremor was controlled. December 1 scopolamine hydrobromide was discontinued and the patient was still ambulatory, though the tremor returned. December 4, phenobarbital was again prescribed, the patient receiving 1 grain daily. The first dose was given at night. The next day the patient complained of difficulty in feeding herself and also of inability to move freely in bed. These symptoms became more marked December 6, and December 7 the dose of phenobarbital was increased to $1\frac{1}{2}$ grains twice a day. At 8 p.m., after the patient had had two tablets, she was unable to get out of bed unaided or even turn on her side and had to be helped with her feeding. When placed on her feet she showed marked festination in walking and would have fallen several times had she not been supported. At this time her condition was similar to what it had been when we first saw her on November 21. She could not stand unassisted and was confined to bed in one constant position because of rigidity. December 9, phenobarbital was discontinued. Four days later the patient was again ambulatory and was discharged from the hospital. She has since been seen in the outpatient department and appears to be no worse for her experience with the phenobarbital.

CASE 3—Man with Parkinson's syndrome of the degenerative type. Rigidity increased with administration of phenobarbital. Return to previous state on discontinuance of medication.

A man, aged 49, a miner, presenting himself at the Los Angeles County General Hospital Nov. 11, 1936, complained of dizziness of one year's duration. This dizziness was relieved by lying down, though it was constantly present in the erect posture. Slowness of movement had been noted for one year and stiffness of the neck for four weeks. The patient during the past year had received antisyphilitic treatment with a bis muth compound, although the Wassermann reaction of the blood had never been positive. There was a history of a penile sore from six to eight years before, which healed in a few weeks and was not followed by secondary lesions. The patient's wife had never been pregnant.

Systemic inquiry further revealed blurring of vision from presbyopia, occasional tinnitus, an intermittent mild cough attributed to cigarettes, dyspnea on exertion in the last year or two, and loss of 15 pounds (7 Kg.) in the last six or eight months. Past illnesses included scarlet fever and typhoid in 1905, bronchitis in 1911, frequent colds, cholecystectomy in 1925, ventral herniorrhaphy, and tonsillectomy in 1926. He was in an automobile accident one year before in which he lost consciousness for one hour, though he suffered no subsequent disability.

On physical examination the temperature was 98 F, pulse 76 and respiration rate 20. The blood pressure was 125 systolic, 95 diastolic, the height 5 feet $6\frac{1}{2}$ inches (169 cm.) and the weight 145½ pounds (66 Kg.). The skin was dry, with seborrheic dermatitis of the chest. There was moderate dental caries. Examination of the neck, lungs, heart and abdomen was negative. The patient showed stooped posture with head and neck held rigid, the arms slightly flexed at the elbows and the fingers flexed toward the palms, he manifested very little change of position over relatively long periods. The facial expression did not vary (typical masked facies). Winking of the eyes occurred infrequently. In walking there was a loss of associated automatic movements in the arms and a tendency toward festination. Both hands exhibited coarse tremor. The

pupils were slightly irregular and reacted sluggishly to light. The deep reflexes were hyperactive. The remainder of the neurologic examination was negative. Laboratory tests, including urinalysis, blood count and Wassermann reaction of the blood and spinal fluid, were normal.

The diagnosis was parkinsonism of the degenerative type. The reference to syphilis and trauma in the history is difficult to evaluate and is not pertinent to the present discussion.

December 2, the patient was given phenobarbital $1\frac{1}{2}$ grains twice a day and seven days later the dose was changed to $1\frac{1}{2}$ grains three times a day. Within a few days the patient began to complain of increasing stiffness. Whereas originally he was able to extend his arms over his head freely, it became increasingly difficult for him to do so. Phenobarbital was maintained until the patient was barely able to raise his arms from the natural position at his sides. Then the phenobarbital was discontinued and two days later the patient was able again to elevate his arms over his head.

CASE 4—*A man with degenerative parkinsonism, who became acutely worse when placed on phenobarbital therapy, $1\frac{1}{2}$ grains twice a day for three days. This was especially noted in his walking.*

This case is not reported in detail because the patient failed to return for complete observation.

CASE 5—*Man presenting Parkinson's syndrome probably due to chronic encephalitis. Increased rigidity manifested after $7\frac{1}{2}$ grains of phenobarbital administered over forty-eight hours.*

I. P., a man, aged 45, Caucasian, a painter and designer, was admitted to the outpatient department at the Los Angeles County General Hospital Jan. 4, 1937, with symptoms of tremor of the right hand and generalized weakness for one and one-half years and tremor of the right lower extremity for one year. These symptoms were slowly progressive, but there was no involvement of the left side. The gait had become slowed and in the last three months there was a tendency to fall forward in taking quick steps. Right parietal headache related to constipation had been present for a year and a half, impaired hearing on the right for six months, and slowing of speech for one month. There were no mental symptoms. Nocturia, from three to four times a night, was noted on systemic inquiry.

In 1917 the patient had influenza in Rumania and was confined to bed for only three or four days but did not regain his previous state of health for two months. There was no diplopia, headache or disturbance of the sleep rhythm. Past and family histories were otherwise irrelevant.

On physical examination the temperature was 97.8 F., pulse 52, respiration rate 18, weight 158 pounds (72 Kg.), height 5 feet 6 inches (168 cm.) and blood pressure 105 systolic, 70 diastolic. There were no signs of arteriosclerosis. The general examination was not noteworthy. There was a flat facies with slowness of both movement and speech. Winking was infrequent. In walking there was no swing in the right arm, which was flexed at the elbow and showed a coarse pin rolling tremor in the fingers, the left arm did swing through a diminished excursion but was not flexed. Rigidity in the right arm and leg was of the plastic type and contrasted definitely with the normal tonicity on the left. In walking there was an intermittent scraping of the right foot. The patient could extend the two hands overhead almost equally, and when lying on his back he could flex the right thigh to an angle of 60 degrees and the left thigh to 90 degrees. In sitting down he assisted himself with both hands. The deep reflexes were active and equal, as were the superficial reflexes. There were no sensory abnormalities and the temperature of the affected extremities was normal. The cranial nerves were also normal except for pupillary inequality (the right being greater), paralysis of ocular convergence and slowness of speech. Urinalysis, and the Wassermann reaction of the blood were negative and the blood count was normal. The diagnosis was encephalitic parkinsonism. No medication was administered. January 11 phenobarbital $1\frac{1}{2}$ grains twice a day was prescribed. January 12 there was no demonstrable change. The phenobarbital was increased to $1\frac{1}{2}$ grains three times a day. January 13 the patient reported more difficulty in walking and numbness of the right lower extremity but slight improvement in the tremor. Objectively, the gait was slower and both feet scraped in walking, there was an increased rigidity in the right arm and leg with an appearance of rigidity in the left leg, an inability to

elevate the right arm as high as the left, a limitation of elevation of the thighs on the right to 45 degrees and on the left to 60 degrees, and a few nystagmoid jerks when he looked to the left. The cogwheel phenomenon was not noted though it had been present previously. January 14 the patient was admitted to the clinic in a wheel chair. The gait had become so bad that he fell for the first time. "My mind and leg don't work together," he complained. He felt that the tremor was improved. Drowsiness and numbness of the right leg were present. He was obviously much slower in all motions. He could elevate the arms and legs about the same as on the previous day, though to a less degree. There was no nystagmus. The phenobarbital was discontinued. January 18 the patient was improved. The rigidity was diminished and he was now able to perform the same degree of movement as previous to the phenobarbital therapy. He was more rapid in his movements and in walking dragged only the right foot. The tremor was slightly increased. There was no rigidity in the left lower extremity.

COMMENT

In view of the foregoing clinical experience, one must conclude that phenobarbital is contraindicated in cases of parkinsonism. The possibility of aggravating the rigidity with moderate therapeutic doses leaves no question as to the undesirable effect of this drug. As yet the minimum adverse dose cannot be stipulated. The effect is presumably the same in all types of the syndrome, although our cases are few, inflammatory, degenerative and arteriosclerotic parkinsonism are included. Since these patients frequently suffer from insomnia, it is not surprising that hypnotics of the barbituric acid group are prescribed. One would surmise that barbiturates have a widespread vogue among these patients. The harmful effect herein recorded definitely indicates the inadvisability of such therapy.

The mechanism of phenobarbital in these cases is of interest. The barbiturates are frequently referred to as brain stem hypnotics. The predilection of these drugs for the basal nuclei of the brain is still a subject of much controversy. Although there are many references in the literature to an affinity of the barbituric derivatives for the central nervous system and even the basal ganglions, only two bits of evidence are pertinent. In the first place, postbarbital parkinsonism has been described as one of the symptoms of overdosage.¹ Secondly, the Keesers² demonstrated experimentally the presence of the chemical salts exclusively in the thalamus and corpus striatum. Koppanyi³ and his associates reported contrary results, for they obtained barbiturates from all parts of the nervous system and also from other organs. The Keesers,⁴ however, in a later communication insisted that small doses were essential to demonstrate a selective affinity as shown in their studies, whereas Koppanyi and his associates used large quantities of the drugs. Whatever one may conclude from a review of the literature treating with selective versus generalized activity of the barbiturates, the fact that in barbital poisoning parkinsonian symptoms do occur throws much light on our problem. With the basal ganglions already diseased in parkinsonism it is easy to visualize the increased disability resulting from drugs acting on the same nuclei, whether or not the drugs have action elsewhere.

Hodskins and Yakovlev⁵ refer to an end stage of physical deterioration in epileptic patients which they characterize as neurosomatic deterioration, the parkinsonian syndrome being the chief feature. One wonders to what extent this late picture may be due to the prolonged use of phenobarbital in epilepsy.

From the diagnostic standpoint one frequently sees patients in the early stages of parkinsonism with the process mild and limited to one extremity, when the diagnosis cannot be made with absolute certainty. At this stage it may be difficult to make a differential diagnosis from multiple sclerosis, prehemiplegic tremor due to neoplasms or other low grade chronic or subacute cerebral processes, and other less common clinical conditions. If phenobarbital has a specific effect on the mechanism of plastic rigidity and not on the other types of rigidity, there may be a diagnostic aid for isolating the early Parkinson cases.

Likewise, from a therapeutic standpoint the question arises as to whether or not physiologic antidotes for the barbiturates may not have a salutary influence in the treatment of this type of rigidity. Studies with regard to these factors are now in progress.

CONCLUSION

Phenobarbital therapy in five cases of parkinsonism has resulted in an aggravation of the rigidity already present. The five cases include the three chief etiologic types of the syndrome. Phenobarbital and probably the other barbiturates as well, are contraindicated in parkinsonism.

LEUKOCYTE BEHAVIOR DURING GASTRIC ANALYSIS

A CRITICAL STUDY OF THE "LEUKO- PENIC INDEX"

CHARLES-FRANCIS LONG, M.D.

PHILADELPHIA

In 1931 Kern¹ suggested that there might be some relation between peptic ulcer and allergy, in 1934 Vaughan² seemed to prove a definite relationship between leukopenia and food allergy, still later Rinkel³ and Zeller⁴ added their similar work, and only last year Gay⁵ stated that peptic ulcer may in some instances be associated with a definite food sensitivity.

It would therefore seem logical to suppose that, if such cases were to be found, they would be open to discovery in a gastro-intestinal clinic, especially such a clinic as ours, which uses the Ewald test meal of bread and water, the bread containing those most usual and powerful allergens milk and wheat.

The problem that presents itself was consequently twofold: to study, first of all, leukocyte behavior during 100 consecutive gastric analyses, with no preconceived bias, with no limitation as to type of case considered or its pathologic classification, but simply with a view to the occurrence of leukopenia and its possible relation-

ship to various acid values. By observing this relationship we would bring ourselves to the second consideration: Shall we abandon the Ewald test meal because its factor of error due to its allergic contents would prove too great a risk to tolerate in modern medicine?

On June 1, 1936, we began our experiments. On June 6, 1936, THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION appeared with an editorial⁶ casting grave doubt on the value of the work of Gay, and by corollary on that also of Rinkel and Vaughan. Now with our series complete, we feel that the results which lie before us conclusively uphold the theoretical prognostications of that editorial.

Turning first to our precursors, the text of Vaughan's research gives as the basis of recognition of an allergen the behavior of the leukocytes during the use of the suspected food as a test meal. In patients who show

Chart 1—Leukopenia with Ewald test alone, leukocytosis with Ewald test plus histamine.

such allergy, a leukopenia of more than 1,000 cells is said to occur within an hour after the ingestion of the offending allergen. Gay further states that in ulcer cases this leukopenic manifestation is also associated with a hypochlorhydria or an achlorhydria.

In order to evaluate the curves formed by these blood counts we turned to the work of Rinkel, whose definitions we were glad to accept for the purposes of this experiment. Based on a series of 5,000 counts, Rinkel has divided the leukocyte responses into three types of curves:

- 1 The compatible curve, which is a leukocytosis of more than 1,000 cells above the mean base line.
- 2 The indeterminate curve, which may swing above or below the base line or show a sort of pendulum effect but does not vary 1,000 cells up or down.
- 3 The incompatible curve which is a leukopenia of more than 1,000 cells below the mean base line.

In composing our experiment, we resolved to control it as closely as possible. A technician whose accuracy in leukocyte counts has been checked and proved in many instances was asked to do all the counts. The technic of Vaughan was carefully carried out. The same pipet was used for each patient. The counts were

⁶ The Leukopenic Index and Food Allergy editorial J. A. M. A. 106: 1933 (June 6) 1936.

done in the same room at the same time on each clinic day, so that as far as possible the psychogenic factor was controlled. The same test meal, the Ewald, was used throughout and the patients consumed it within relatively the same space of time. Those patients who showed an achlorhydria were requested to return for

Chart 2—Leukopenia with Ewald test alone. Slight leukopenia with Ewald test plus histamine. Leukocytosis with alcohol meal.

a recheck with not only the same test meal but also a hypodermic injection of histamine. When possible, we attempted a further check using alcohol as the test meal.

RESULTS

In this series of 100 patients we performed 113 fractional gastric analyses with 678 simultaneous complete leukocyte and differential counts, one at each fractional withdrawal. Of our 100 patients, thirteen showed achlorhydria, twelve showed hypochlorhydria, thirty-five showed euclorhydria and forty showed hyperchlorhydria.

Since the differential counts did not vary significantly from one period to another, thereby giving no diagnostic information, we agreed to discard them.

TABLE 1—Total Leukocyte Behavior

	Totals	Achlor hydria	Hypo chlor hydria	Euclor hydria	Hyper chlor hydria
Number of cases	13	12	30	40	
Indeterminate curves	21	15	7	14	15
Compatible curves	27	3	2	10	12
Incompatible curves	35	4	3	15	13
	113	22	12	39	40

Turning first then to the total leukocyte behavior, one finds that seventy-eight of the curves, or 69 per cent, fell into the indeterminate (fifty-one) and compatible (twenty-seven) groups which percentage held true as a general rule in all four groups of acid curves (table 1). This, by the criteria of Rinkel, leads to the inference that seven out of ten patients complaining of gastro-intestinal symptoms do not have evidence of allergy to the Ewald test food. But when one looks to the three out of ten who showed incompatible curves in this study, one fact becomes promptly apparent. As, in table 1, one proceeds from the achlorhydric through the hypochlorhydric and euclorhydric groups on up to the hyperchlorhydric, one finds an ascending percentage of incompatible curves: achlorhydria 18 per

cent, hypochlorhydria 25 per cent, euclorhydria 33 per cent, hyperchlorhydria 38 per cent. This, then, is the only relationship we could discover between leukopenia and the acid value and it seems to be the exact opposite of that promulgated by Gay.

This, however, is only an apparent relationship, for in the individuals studied the leukocytes behaved in an absolutely unpredictable manner. Of several achlorhydric patients

1. A patient with the Ewald test alone showed a leukopenia 2,100 cells below the mean. Then with Ewald plus histamine a leukocytosis 1,800 above the mean (chart 1).

TABLE 2—Acid and Leukocyte Relationships in Proved Peptic Ulcer

	Totals	Achlor hydria	Hypo chlor hydria	Euclor hydria	Hyper chlor hydria
Number of cases	14	0	1	5	8
Incompatible curves	7	0	0	2	5
Indeterminate curves	2	0	1	1	0
Compatible curves	5	0	0	2	3

2. Another patient with the Ewald test alone showed a leukopenia of 1,100 cells below the mean. With the Ewald test plus histamine the leukopenia was only 300 cells. With the alcohol meal there was a leukocytosis of 900 cells (chart 2).

3. A third patient had a leukopenia of 2,100 cells below the mean the first hour and a leukocytosis of 900 cells the second hour with the Ewald meal. With the Ewald plus histamine the leukopenia was 1,900 cells. When alcohol was used there was a leukocytosis of 2,100 cells (chart 3).

4. Finally, a patient with the Ewald meal showed a leukocytosis of 700 cells, but when the Ewald plus

Chart 3 Leukopenia the first hour and leukocytosis the second hour with Ewald meal. Leukopenia with Ewald test plus histamine. Leukocytosis with alcohol.

histamine was used a leukopenia of 700 cells developed (chart 4).

Then, if one follows the criteria of Rinkel, one must believe from the figures here compiled that one out of four hypochlorhydric patients, one out of three of those with normal acid values and two out of five hyperchlorhydric patients are allergic to the bread in the Ewald test meal. In view of the individual variations

that have been detailed, this cannot be accepted as true or constant but merely a variation in the blood of that patient at the particular time the test was carried out. So believing, one can continue to use the Ewald test meal as a routine in gastric study.

To the further credit of this meal may be cited the fact that 13 per cent of the patients had a constant unvarying and complete achlorhydria in spite of histamine, and in those few who submitted to recheck with the alcohol meal regardless of that too.

PEPTIC ULCER AND LEUKOCYTE BEHAVIOR

In this series of 100 patients, fourteen had proved peptic ulcer. Of these, none had achlorhydria, one had hypochlorhydria, five had euechlorhydria and eight had hyperchlorhydria.

The incompatible leukocyte curves numbered seven, five of them associated with hyperchlorhydria and two with euechlorhydria. In no instance did we find an incompatible curve associated with hypochlorhydria or achlorhydria.

Chart 4—Leukocytosis with Ewald meal. Leukopenia with Ewald meal plus histamine.

There were five compatible curves, three with hyperchlorhydria, two with euechlorhydria. Indeterminate curves were obtained in one euechlorhydria and one hypochlorhydria.

In Gay's six ulcer cases, incompatible curves were obtained in every instance with milk and wheat. Here are incompatible curves with the same allergens in exactly 50 per cent of the cases.

CONCLUSIONS

1 With the technic of Vaughan and the criteria of Rinkel, a study was made of 100 unselected patients from a gastro-intestinal clinic. By means of leukocyte counts during gastric analysis we attempted to survey any possible constant relationship existing between the acid values and leukocyte behavior. We could find none.

2 In this series were found fourteen patients with proved peptic ulcer. In these, too, we could find no constant relationship between acid values and the leukocyte counts.

Clinical Notes, Suggestions and New Instruments

A PATIENT WITH PICK'S DISEASE BENEFITED BY TWO CARDIOLYSIS OPERATIONS TWENTY-ONE YEARS APART

KENNETH B. TURNER, M.D., AND RICHMOND L. MOORE, M.D.
NEW YORK

The patient, who is an Italian-born housewife, was first admitted to the Presbyterian Hospital in April 1914, at the age of 25. Her previous health had been good except for a week in 1906 when she had been kept in bed because of severe pain in the region of the heart and in the left lower chest posteriorly. Further details of this illness are lacking. She had married in 1908 and had had three pregnancies. The first two infants had died shortly after birth. The third was well and vigorous at the age of 2 months.

Six months before admission and while pregnant for the third time, she had caught a severe cold with a troublesome cough. Following this she developed swelling of the feet and legs, which did not grow worse until after delivery, then when she got up and walked about the swelling increased greatly. She became nervous and complained of palpitation and various vague pains.

On admission it was noted that she was pale. There were rales at both lung bases. The heart was enlarged and there was a diffuse apical systolic retraction. Broadbent's sign was present. There were no murmurs, but the second sound at the apex was reduplicated, producing a gallop rhythm. The blood pressure was 114 systolic, 60 diastolic. There was marked ascites. The liver and spleen were enlarged. The legs and thighs showed massive edema. She had a mild hypochromic anemia with leukopenia and there was a faint trace of albumin in the urine. The blood Wassermann reaction was negative.

A diagnosis of adherent pericardium was made and it was thought that she might be benefited by a cardiomyolysis. Accordingly, a month after admission, a chondrectomy with removal of the third to sixth costal cartilages was performed by Dr. Ellsworth Eliot. At operation the pericardium was found to be thickened and adherent to the anterior chest wall. She stood the operation well, the postoperative course was uneventful and she was discharged six weeks later. At discharge she was in excellent condition. No edema or ascites was present. The liver and spleen remained enlarged.

Five months after her discharge from this hospital she had a ventral fixation of the uterus at another institution. For the next ten years she remained symptom free. During this period she was twice pregnant. The first time she had a normal child, the second pregnancy ended in a miscarriage. She became pregnant again and this time she had a difficult labor with an instrumental delivery resulting in the death of the child. She remained in bed for ten days following this and then began to get up about the house. Thereupon her abdomen began to swell and she felt weak. These symptoms progressed during the next month and she again sought admission to the hospital. This was in April 1925.

On examination there was rather marked pallor. The chest showed the old operative scar. There were a few rales at the left lung base. The heart was enlarged to the left by percussion. It was slow and regular. The sounds were of good quality except that the second sound at the apex was strongly reduplicated, producing a gallop rhythm. There was an apical systolic retraction and a positive Broadbent sign. No cardiac murmurs were heard. The blood pressure was 104/60. The abdomen was distended. A fluid wave was easily obtained and there was shifting dullness in the flanks. The liver was 9 cm. below the costal margin, firm, smooth and not tender. The tip of the spleen was just palpable. There was no edema of the ankles or over the sacrum.

A blood count showed 38 million red blood cells with a hemoglobin of 50 per cent. The leukocytes numbered 4,000 with a normal differential count. In the blood smear the red cells varied slightly in size and shape, were rather achromic, and rare nucleated forms were seen. A slight albuminuria was

present consistently, but the urine was otherwise normal. The blood urea was 32 mg per hundred cubic centimeters. The blood Wassermann reaction was again negative and the serum was negative for bile. An intracutaneous tuberculin test was negative. A stereoscopic roentgenogram of the chest showed shadows obliterating both costophrenic angles suggesting a small amount of fluid. There also seemed to be some thickening of the pleura at the right base. Electrocardiographic study showed a few ventricular premature beats on one occasion, a right axis deviation, and only slight change in the electrical axis of the heart when tracings were taken with the patient on her back and on her right and left sides.

The day after admission, 4,500 cc of cloudy greenish yellow fluid, which had a specific gravity of 1.017, was removed from the peritoneal cavity. There were 90 cells per cubic millimeter, of which 75 per cent were lymphocytes and the remainder polymorphonuclear leukocytes. The fluid was sterile on culture but was not injected into a guinea-pig. Following the paracentesis she improved rapidly with bed rest alone. Her course was afebrile. She was discharged after six weeks in the hospital, having been ambulatory for some time without reaccumulation of fluid.

She visited the follow-up clinic at intervals for about a year. Physically she was well during this time, but she developed a mental depression that required the supervision of a psychiatrist. She then failed to visit the hospital for seven years. She reappeared in June 1933 stating that she had been well until a month before, when she had slipped and fallen down a flight of stairs. Following this her legs began to swell. The swelling had progressively become worse, the abdomen had swollen and she had become weak, somewhat dyspneic and slightly nauseated after eating even small amounts of food. She was found to have marked ascites and some edema over the sacrum but not of the legs. The neck veins were somewhat distended. Her heart was as before, the usual rales were heard at the left lung base, the liver and spleen were again readily palpable.

She was readmitted to the hospital but remained only two weeks. On this occasion she was not anemic. The leukopenia persisted. Slight albuminuria was again present. Galactose tolerance and bromsulfalein tests of liver function showed it unimpaired. The serum protein was 4.1 per cent. The sedimentation rate of the red blood cells was 8 mm in one hour. Electrocardiograms showed that right axis deviation was still present and that there was a considerable shift in the electrical axis when films were taken in three positions. A roentgenogram gave evidence of calcification in the pericardium. The venous pressure was 117 mm of water on admission, dropping to 65 mm with improvement.

With bed rest the edema and ascites disappeared rapidly. She lost 9 pounds (4 Kg) in a week, and after another week she was discharged in good condition. For the next fifteen months she remained well. She then began to have vague abdominal pain and developed edema and ascites which increased steadily in amount in spite of bed rest. Left pleural pain with a loud pleural friction rub appeared. Finally, in February 1935, she was again admitted.

On this occasion her physical examination was much as it had been on previous admissions. The neck veins were not prominent. Again dulness and rales were found at the left base. The heart had the same reduplicated second sound causing a gallop rhythm and there was a marked systolic retraction at the apex. The abdomen was protuberant as the result of ascites. The liver and spleen were enlarged as before. There was edema of the legs and over the sacrum. The blood pressure was 100/70.

The hemoglobin was 75 per cent with 5 million red blood cells. The leukocytes numbered only 3,200 with a normal differential count. The sedimentation rate was 9 mm. Albuminuria was no longer present. The serum nonprotein nitrogen was 24 mg per hundred cubic centimeters. A hypoproteinemia was again present with a serum protein of only 3.8 per cent. A protein partition was not done. The intracutaneous tuberculin test again was negative. The venous pressure was not elevated, measuring 90 mm of water. The electrical axis of the heart as determined by electrocardiography shifted with change in the position of the patient. Calcification was again noted in the pericardium by x-ray examination and in the lungs there was calcification at both hili, more on the left with thickening of the pleura at the left base. The parenchyma of the lungs was clear. The heart seemed definitely enlarged.

The right border was a maximum of 62 cm from the mid sternal line, the left border was 98 cm. The total transverse diameter of the heart was thus 16 cm, while the internal diameter of the chest measured 26 cm. There had been no increase in the heart size, however, since 1933.

With bed rest, restriction of fluids and a high protein low salt diet she had a prompt diuresis. Edema and ascites decreased markedly, her weight fell from 104 pounds (47 Kg) to 87½ pounds (40 Kg), the serum protein rose rapidly to 7.3 per cent. However, because of her increasing tendency to develop ascites even when resting at home, because of her favorable response to her previous operation twenty-one years before, and because of the obvious systolic retraction at the apex with evidence of regeneration of the ribs previously removed it was decided that another cardiomyolysis should be attempted. This accordingly was performed in March 1935, six weeks after admission by one of us (R. L. M.) whose note follows.

This case was considered a suitable one for the Brauer type of operation because there was a systolic retraction of the left anterior chest wall with each heart beat. This was especially pronounced just lateral to the previous scar. The costal cartilages which had been resected by Dr. Eliot had regenerated almost entirely as bone. However, there was some cartilage connecting the fifth rib with the sternum, which had probably been left behind at the previous operation. The heart appeared to be enlarged and there was a dense scar in the anterior mediastinum binding the heart and pericardium to the sternum just lateral to the midline opposite the fifth intercostal space. The pericardium adjacent to the scar did not appear abnormal and the motion of the heart underneath appeared to be free. At the site of the scar there was an irregular, firm mass which was thought to be the area of calcification that had been seen in the x-ray films. There did not appear to be any pericardial effusion. The anterior sulcus of the left pleura appeared to be free because the lung could be seen to glide back and forth underneath.

The patient was given tribrom-ethanol by rectum (90 mg per kilogram of body weight) as a basal anesthetic. This was supplemented by the local infiltration of procaine. The incision began at the level of the second intercostal space just off the midline of the sternum, extended downward along the line of the previous scar to the fifth space and was then carried laterally along the fifth space to about the nipple line. A skin and muscle flap thus outlined was reflected upward and laterally and sections of the fifth, fourth and third ribs, each approximately 1 inch in length, were resected from the underlying pleura and pericardium. The dissection was carried medially to the sternum, and a small portion of the lateral border of the sternum was also removed. As a result of this the rigidity of the thoracic wall over the area of the adherent pericardium was removed. Then the internal mammary vessels were ligated and the periosteum was excised from the several rib beds. After the flap had been replaced the wound was closed without drainage. The patient stood the procedure well and was in good condition at the end.

The postoperative course was uneventful. The patient was discharged a month after the operation.

During the twenty-two months that have elapsed since the second cardiomyolysis her physical condition has remained extremely satisfactory. There has been no recurrence of ascites or edema. Blood counts have been normal except for a persistent leukopenia. The sedimentation rate has been normal. The urine is normal. Determinations of the nonprotein nitrogen, bilirubin, protein, calcium and phosphorus in the serum have all yielded normal results.

Despite her excellent physical condition she had a recurrence of profound melancholia about a year ago that led to an attempt at suicide following which she was admitted to a hospital for mental disease, where she remained for about three months. She has been more cheerful recently and well able to perform the daily tasks about her home.

She was last seen here Jan. 6, 1937, at which time she looked and felt pretty well. She was doing her housework and did not have undue fatigue. Her only complaint was constipation. There was no dyspnea, orthopnea, cyanosis, venous distention or edema. The heart was slow and regular. There was a gallop rhythm due to a reduplicated second sound. No murmurs were present. There was marked systolic retraction in the

operative area. The blood pressure was 120/80. The right lung was clear. There were many coarse rales at the left base. There was no ascites. The liver was down the breadth of one finger in the midclavicular line and of three fingers in the midline. It was smooth and not tender. The spleen tip was just felt. A blood count was made and showed hemoglobin 81 per cent, red cells 5.2 million, white cells 5,400 and a normal differential.

COMMENT

For want of a better term this case has been classified as an example of Pick's disease with mediastinopericarditis, some basal pleurisy on the left side, enlargement of the liver and to a lesser extent of the spleen, and recurrent ascites. It seems likely that there is not complete obliteration of the pericardial sac because of the observations at the time of the last operation. Absence of obstruction to the return of blood by the superior vena cava is shown by the lack of permanent elevation of the venous pressure in the arms. Unfortunately, no determinations of the venous pressure in the legs were made. As is usual in these cases, the inferior vena cava has been chiefly affected resulting in marked hepatic enlargement and ascites out of all proportion to the rest of the picture. The prompt improvement twice manifest after cardiolysis suggests that the obstruction of the inferior vena cava may have been due to some torsion effect or kinking as the result of dense adhesions between the pericardium and the anterior chest wall.

The etiology of the pericardial lesion in this case is unknown. There is no evidence of tuberculosis. The intracutaneous tuberculin test has been negative twice. There is no rheumatic history, no valvular involvement, and no electrocardiographic evidence of myocardial damage.

Perhaps the long survival of the patient has been due to the fact that she was peculiarly amenable to surgical relief by the Brauer operation because the mediastinopericardial adhesions, while extremely dense and partially calcified, were limited in extent and maximal in the region of the cardiac apex beneath the ribs that were resected.

SUMMARY

A woman, aged 48, with Pick's disease, had two cardiolysis operations twenty-one years apart and is alive and well twenty-three years after the first and nearly two years after the second operation.

IMPENDING GANGRENE OF THE FEET DUE TO
ERGOTAMINE TARTRATE

REPORT OF A CASE TREATED SUCCESSFULLY

SAMUEL PERLOW M.D. AND LEON BLOCH M.D. CHICAGO

There are two forms of ergotism, the gangrenous and the convulsive types. The former occurs usually in the extremities and may result in the loss of fingers and toes and sometimes of an entire extremity. Gangrene of the internal organs also may occur. The convulsive type of ergotism is believed to be due to some action on the central nervous system and is manifested by depression, weakness, headaches, and finally tonic and clonic convulsions. Chronic ergotism has occurred in epidemic form in eastern Europe for centuries following the ingestion of bread made of ergot-infested rye. The last epidemic of chronic ergot poisoning from this cause in the United States occurred in New York in 1825. Acute ergotism is similar to the chronic form but of a more rapid onset and development. It occasionally follows the therapeutic use of ergot and its derivatives especially ergotamine tartrate. The smallest amount of ergotamine tartrate that has sufficed to produce gangrene was 1 mg given subcutaneously¹ over a period of four days and 26 mg given orally² in one week.

The treatment of the gangrenous form of ergotism has been unsatisfactory and no instance of complete cure has been reported following any treatment. Speck³ reports a case which

he believes was definitely helped by the use of theophylline but in his case there was residual gangrene of a toe and part of the foot. Platt⁴ also reports a case of gangrene of the toes with a slow recovery which he believes was helped by the use of scopalamine. Epinephrine has been used in several cases with poor results. In a large series of cases recently reported by O'Sullivan⁵ in which ergotamine was used for migraine, the deleterious effects were believed to have been prevented by the use of atropine and calcium.

TABLE 1—Condition of Patient September 2

General appearance		
Skin slightly icteric, numerous scratch marks on both feet and legs. No trophic changes in skin and nails. Hair present on all toes. All toes blanched in spots and cyanotic to their bases. This was most marked in the big toes. All discolored areas cold and numb.		
Arterial pulsations		
Femoral	++++	++++
Popliteal	+	+++
Dorsalis pedis	0	0

Dorsum of foot	28.4	29.3
Plantar surface	27.3	28.3
End of first toe	25.4	27.2
Room temperature C	20.5	

We are reporting this case of ergotamine tartrate poisoning with impending gangrene of both feet because of the rapid and complete cure without any gangrene which was obtained by the use of papaverine hydrochloride.

REPORT OF CASE

History.—J. S., a white man, aged 36, was admitted to the Michael Reese Hospital Aug 12, 1936. His main complaints were jaundice of one month's duration and generalized pruritus for two years. In March 1935 after he had had pruritus for six months he consulted one of us (L. B.), who made a diagnosis of Hodgkin's disease, which was subsequently verified by a biopsy examination of a cervical lymph gland. In the next one and one-half years he was given several courses of x-ray therapy over the cervical lymph glands and spleen, which caused an improvement in his general condition and disappearance of the glandular enlargement. The pruritus however, persisted although in a much milder form. About one month before admission, pain developed in the epigastrium, which was soon followed by a progressively increasing jaundice and the pruritus became very much worse. The remainder of the history was essentially negative.

Examination.—On admission, the patient appeared fairly well nourished and was moderately jaundiced. The temperature was 98.8 F., pulse 82, respiration 18, blood pressure 150 systolic, 76 diastolic. Physical examination was essentially negative except for a chain of enlarged, firm lymph nodes behind the right ear and under the mandible and several in the left posterior cervical chain. There was moderate enlargement of both the liver and spleen and slight tenderness on deep palpation over the epigastrium. There were a few small firm inguinal lymph glands. The blood Kahn reaction was negative. Hemoglobin was 80 per cent, the erythrocyte count 3,640,000 and the leukocyte count 10,600. Differential white blood count showed 86 per cent polymorphonuclear cells, 4 per cent lymphocytes and 10 per cent monocytes. The urine was acid, the specific gravity was 1.006, it was negative for sugar and acetone, positive for urobilinogen, and there was a trace of albumin. The stool was formed and tan colored, the reaction for bile was positive and for blood and parasites negative. The blood icterus index was 39, blood sugar 71 mg per hundred cubic centimeters of blood and nonprotein nitrogen 50.

Course—The condition of the patient became progressively worse. To relieve the intolerable pruritus, ergotamine tartrate therapy was started August 21, when the patient was given 1 mg of ergotamine tartrate (one tablet) by mouth. He refused all further medication until August 26 when ergotamine tartrate was administered subcutaneously. He was given 0.5 mg (two ampules of 0.25 mg each) subcutaneously August 26, 27 and 28, 0.25 mg (one ampule) August 29, 0.5 mg August 30 and 0.25 mg August 31. The pruritus disappeared.

TABLE 2—Condition of Patient September 3

General appearance		
The patient had no pain in the feet and the sensations of coldness and numbness had disappeared. The toes were pink. There was no cyanosis or blanching.

on the latter date and the ergotamine therapy was discontinued. The patient received altogether 1 mg of ergotamine tartrate (one tablet) by mouth and 2.5 mg (ten ampules of 0.25 mg each) subcutaneously. On the evening of August 31 the patient began to experience pain in the toes, which became worse very rapidly. It became so intense that on September 1 he required seven 0.01 Gm doses of morphine sulfate hypodermically for relief. At the onset of his pain the toes were cold and slightly edematous. September 1 the skin of the toes became cyanotic. The condition on examination of the extremities at 9 p m September 2 was as outlined in table 1.

A diagnosis was made of spasm and possibly beginning organic occlusion of the arteries of both feet with impending gangrene due to ergotamine tartrate.

The patient was given one-half grain (0.03 Gm) of papaverine hydrochloride, dissolved in 1 cc of physiologic solution of sodium chloride intravenously at 10:30 p m September 2, one-half grain was given by mouth at 4 a m September 3 and one-half grain intravenously at 8 a m. A hypodermic injection of morphine sulfate 0.015 Gm was given at 2 a m because of restlessness and very slight pain in the right foot. Examination of the patient at 10 a m September 3, about twelve hours after treatment was begun, revealed a marked improvement in the condition of his feet. The condition was as given in table 2.

Papaverine hydrochloride one-half grain (0.03 Gm) was administered intravenously again at 2 p m and 8 p m September 3 and by mouth twice September 4 and once September 5. In addition to the papaverine hydrochloride therapy the lower extremities were treated with the suction and pressure boot for five hours September 3, four hours September 4 and two hours September 5. This therapy was started and given as good measure after the improvement had taken place following the administration of the papaverine hydrochloride and after the examination had been made. The extremities remained normal after all treatment was stopped. There was no loss of tissue, no discoloration and no impairment of sensation.

For the general condition which was believed to be due to lymph glandular enlargement at the liver hilus the patient was given x-ray therapy over the liver region. The jaundice disappeared almost completely and the patient was discharged September 19.

COMMENT

The pathogenesis of gangrene in ergot intoxication has been demonstrated⁶ to be a primary vascular spasm followed by

thrombosis due to stasis and injury of the intima. Because of some good results that we had obtained by the use of papaverine hydrochloride as an antispasmodic in other types of peripheral circulatory disturbances, we decided to use it in the treatment of this patient. Later we discovered that Yater⁷ mentioned this drug among others that should be used in the treatment of ergotism. A complete review of the literature, however, reveals no instance of its actual use in a case of ergotism prior to our report.

The results obtained in this case of marked arterial spasm with impending gangrene within twelve hours after starting the use of papaverine hydrochloride were so dramatic as to leave no doubt in our minds of the efficacy of this drug as a vascular antispasmodic. For forty-eight hours after ergotamine tartrate was discontinued the patient's condition became worse steadily, the toes became blue, cold and lifeless, and arterial pulsations were absent in the feet. The pain in the feet due to ischemia was so intense that the patient required as much as seven hypodermic injections of morphine sulfate of one-fourth grain (0.015 Gm) each within twenty-four hours for relief. Following the intravenous administration of one-half grain of papaverine (0.03 Gm) the condition quickly improved and, although the patient received morphine for restlessness and slight pain in the right foot three hours later, in twelve hours the pain was gone entirely, the arterial pulsations returned and the toes appeared normal. The results were so complete at that time that we believe that the suction and pressure treatment which was given subsequently was of negligible value in this case.

The value of papaverine hydrochloride as an antispasmodic in other types of peripheral arterial disease has been described previously.⁸ The result obtained in our case is additional evidence of the ability of this drug to relax arteries in a state of spasm.

SUMMARY

In a case of ergotamine tartrate poisoning with impending gangrene of the feet, a complete cure was brought about by the use of papaverine hydrochloride.

185 North Wabash Avenue—310 South Michigan Avenue

FASCIAL HERNIA OF BOTH LOWER EXTREMITIES
INJECTION WITH SODIUM MORRHUATE

ADOLPH A. SCHMIER, M.D., NEW YORK

This is a case of fascial defect on the anterolateral aspect of the lower third of both legs. Because of this fascial defect a herniation of the underlying muscle resulted. Since the pain and disability were effectively relieved by injections of sodium morrhuate, I feel that this case is of interest to report.

I K., a youth, aged 21, first seen in the varicose vein clinic of Dr. I. S. Tunick at the Hospital for Joint Diseases, complained of pain in both legs and feet especially when engaged in sports or fast walking. The pain had first come on about four years before while the patient was playing basketball. At that time he noticed a lump on the outer lower aspect of each leg. A throbbing pressure pain would begin at these sites and radiate down to the feet. Gradually the pain became so severe that he had to discontinue sports of all kinds.

Examination revealed a localized bulging on the anterolateral aspect of the lower third of each leg about 5 inches (13 cm) above the level of the ankle joint. The overlying skin was not discolored. The masses had a soft doughy consistency and could be invaginated with the palpating finger. No tenderness was present. When full weight was borne on the legs, the bulging became more prominent. As weight was removed from either leg, the bulging disappeared and a dimpling occurred. Active use of the extensor digitorum longus muscle also caused the mass to disappear, replaced by dimpling. The fascial defect was present over the extensor digitorum longus muscle.

A needle was inserted into both areas, but nothing could be aspirated. The feel was not that of a lipoma but rather the

sensation of a needle in empty space. Oct 10, 1935, he received 2 cc of sodium morrhuate into the left hernial space. Only slight pain was experienced. October 17 the left herniation had practically disappeared. The area was quite firm and only slight dimpling could be obtained. Two cubic centimeters of sodium morrhuate was now injected into the right hernia and 1 cc into the left. A total of four injections amounting to 6 cc of morrhuate was given into the left leg and two injections totaling 4 cc of morrhuate into the right leg. Jan 13, 1936, both sites were firm. The patient had no pain and was able to play professional basketball again.

October 1, he returned complaining of slight swelling and mild pain in both legs. For almost one year he had been playing basketball without any discomfort. He is still playing basketball but returns for further injections in order to avoid more severe disturbance. Examination now revealed only slight prominence on each leg. Five injections totaling 9 cc of sodium morrhuate were required to obliterate the hernial defect on the left leg and two injections totaling 3 cc on the right leg. The mild pain disappeared.

Whether the hernial defects will remain obliterated by the injection method is conjectural. It did give this patient complete relief for almost a year, allowing him to return to competitive sports. Even at the end of this period he was still more comfortable than when first seen. He was still able to compete in sports and returned for further treatment only to avoid his original disability. Possibly an open fascial plastic operation¹ would give a more permanent result, but in cases in which open operation is refused the injection method will be of aid. Apparently the morrhuate sets up a local irritation, producing a fibrosis, which closes over the defect.

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

PAUL NICHOLAS LEECH, Secretary

DIGITALIS (See New and Nonofficial Remedies, 1937, p 180)

The following dosage forms have been accepted

- Tincture Digitalis Upsher Smith* Each cubic centimeter represents 1 U S P unit
Tablets Digitalis Upsher Smith $\frac{1}{2}$ grain Each tablet represents one third U S P unit
Tablets Digitalis Upsher Smith 1 grain Each tablet represents two thirds U S P unit
Tablets Digitalis Upsher Smith $1\frac{1}{2}$ grains Each tablet represents 1 U S P unit
Capsules Digitalis Upsher Smith $\frac{1}{2}$ grain Each capsule represents one third U S P unit
Capsules Digitalis Upsher Smith 1 grain Each capsule represents two-thirds U S P unit
Capsules Digitalis Upsher Smith $1\frac{1}{2}$ grains Each capsule represents 1 U S P unit

Prepared by Upsher Smith Co. Minneapolis Minn

BURBOT LIVER OIL—The oil extracted from the livers of the Burbot (*Lota maculosa*), family Gadidae. It is biologically assayed to have a potency of not less than 4,480 units of vitamin A (U S P) per gram and of not less than 640 units of vitamin D (U S P) per gram.

Actions and Uses—Same as those of cod liver oil. See general article Fish Liver Oils, Preparations and Concentrates, N N R 1937, p 457.

Dosage—Prophylactic, 16 minims (40 drops) daily, or as prescribed by the physician. The product is marketed with a dropper designed to deliver 25 drops to the minim.

Burbot liver oil is a pale yellow oily liquid. It has a slightly fishy but not rancid odor and a fishy taste. It is slightly soluble in alcohol but is soluble in ether, chloroform, benzene, carbon disulfide and ethyl acetate. The specific gravity is from 0.921 to 0.927 at 25 C. The refractive index is from 1.479 to 1.482 at 20 C.

A solution of one drop of the oil in 1 cc of chloroform when shaken with one drop of sulfuric acid acquires a light violet color changing to violet dark green and finally brown. Treat 5 cc of oil with 5 cc

of benzene and centrifugate for twenty five minutes at 25 C. no precipitate forms and a clear solution remains.

Fill a tall cylindric standard oil sample bottle of about 120 cc capacity with burbot liver oil at a temperature between 23 and 28 C. stopper and immerse the bottle in a mixture of ice and distilled water for five hours. The oil remains fluid and forms no deposit.

Dissolve 2 Gm of burbot liver oil accurately weighed in 20 cc of a mixture of equal volumes of alcohol and ether which previously has been neutralized with tenth normal sodium hydroxide using five drops of phenolphthalein T S as indicator and titrate with tenth normal sodium hydroxide to the production of a pink color which persists for fifteen seconds. Not more than 1 cc of tenth normal sodium hydroxide is required (free acid). The amount of unsaponifiable matter is determined by the method of U S P XI, page 446 is not less than 0.9 per cent nor more than 3.0 per cent. The saponification value as determined by the method of U S P XI, page 445 is not less than 184 nor more than 196. The iodine value as determined by the method of U S P XI, page 445 on 0.18 to 0.20 Gm of sample accurately weighed is not less than 155 nor more than 180.

Burbot Liver Oil (Rowell)—A brand of burbot liver oil. N N R

Manufactured by Burbot Liver Products Co. Baudette Minn. No U S patent or trademark.

Capsules Burbot Liver Oil (Rowell) 8 minims. Each capsule contains burbot liver oil (Rowell) 8 minims adjusted to have a potency of not less than 2,215 units of vitamin A (U S P) and 315 units of vitamin D (U S P).

SILVER PICRATE—Silver trimetaphenolate— $C_6H_4(OAg)(NO)_2 + H_2O$

Actions and Uses—Silver picrate has actions and uses similar to those of the other simple silver salts. Its crystals are available for making solutions of appropriate strength. It is also used in the form of a compound powder for the treatment of *Trichomonas vaginalis vaginitis*. This compound powder contains 1 per cent silver picrate in purified kaolin. It is administered by means of an insufflator or other surgical "powder blower". Another dosage form is intended primarily to be used as an adjunct in the treatment of this condition—vaginal suppositories containing 2 grains (0.13 Gm) in a boroglyceride gelatin base. Protracted use of this compound over a long period may possibly give rise to argyria because of its silver content and nephritis because of its picric acid content. It is therefore necessary to watch the skin for signs of argyria, and the urine for albumin and casts.

Dosage—Dilutions of from 1 to 2 per cent are used in the form of solution, compound powder and vaginal suppositories.

Silver picrate occurs as yellow crystals, slowly discoloring in sunlight. It is sparingly soluble in water and alcohol, slightly soluble in acetone and glycerin, very slightly soluble in chloroform and ether.

Dissolve about 0.1 Gm of silver picrate in 10 cc of water, add 1 cc nitric acid followed by the addition of 5 cc of dilute hydrochloric acid, shake thoroughly, filter through paper. The precipitate is soluble in an excess of ammonia water while the filtrate turns red on the addition of ammonia water and ammonium sulfide.

Dissolve an accurately weighed quantity of the material in water about 150 parts, collect the insoluble residue on an ashless filter paper, wash with water using about 300 cc and ignite. The weight of ash on ignition does not exceed 0.5 per cent. To the foregoing filtrate add 2 cc of nitric acid followed by the addition of 5 cc of dilute hydrochloric acid in small quantities with constant stirring. Boil allow to cool, collecting the precipitate of silver chloride on a Gooch crucible, wash with a diluted nitric acid and water followed by the addition of a small quantity of alcohol and ether, finally dry to constant weight at 120 C. the amount of silver calculated from the silver chloride found corresponds to not less than 30 per cent nor more than 32 per cent.

Silver Picrate-Wyeth's—A brand of Silver Picrate. N N R

Manufactured by John Wyeth & Brothers Inc. Philadelphia

Silver Picrate Crystals

Silver Picrate Vaginal Suppositories 2 grains of silver picrate N N R in a boroglyceride gelatin base.

Compound Silver Picrate Powder 1 per cent of silver picrate N N R in purified kaolin.

DIPHTHERIA TOXOID, ALUM PRECIPITATED (REFINED) (See New and Nonofficial Remedies 1937, p 401)

Eli Lilly & Co., Indianapolis

Combined Diphtheria Toxoid Tetanus Toxoid Alum Precipitated Lilly

—A combination of diphtheria toxoid and tetanus toxoid which has been precipitated with alum. The amount of each ingredient in a single dose is the same as that present in a single dose of the individual marketed products. It is prepared by mixing suitable amounts of diphtheria toxin and tetanus toxin which have been detoxified by the use of formaldehyde and precipitating from this combination with alum the diphtheria toxoid and tetanus toxoid. The individual toxoids are tested for toxicity prior to mixing and the combined alum precipitated toxoid is tested for toxicity after precipitation. Potency of the preparation is tested by injecting guinea pigs weighing approximately 500 Gm with one human dose. At the end of four weeks blood serum of guinea pigs so injected must show at least 2 units of diphtheria antitoxin and 1 unit of tetanus antitoxin per cubic centimeter. Combined diphtheria toxoid tetanus toxoid alum precipitated is recommended for the production of active immunity of diphtheria and tetanus. The first dose (0.5 cc) is injected subcutaneously preferably in the region of the deltoid followed in approximately two to three months with a second and final injection of 0.5 cc.

Marketed in packages of one immunization treatment containing two 0.5 cc vials.

Council on Foods

THE COUNCIL ON FOODS HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT
FRANKLIN C. BING, Secretary

THE ALLEGED DECALCIFYING EFFECT OF CEREALS

In 1921 Mellanby¹ produced rickets in puppies by restricting them to a diet of milk and oatmeal. He found that increasing the amount of oatmeal and decreasing the amount of milk in the diet produced a more severe degree of rickets. Other cereal products had a similar effect. He concluded that cereals contained some anticalcifying substance the toxic effect of which could be overcome by the addition of certain foods that contained a calcifying substance. Later it was shown by McCollum and his collaborators that the so-called calcifying substance could be classified with the vitamins and it was given the name of vitamin D. Because of Mellanby's work the idea persisted particularly in England that cereal products contained a substance which had an inhibiting effect on the calcification of bone, a hypothesis that has gained credence perhaps by reference to the alleged substance as a "toxamin". In all cases, however, investigators have agreed that the "baneful effect" attributed to the toxamin could be counteracted with vitamin D.

Because cereals make up so large a part of the diet of the adult, it is important to inquire into the experimental evidence in support of the contention advanced by some persons that cereal products should be treated to overcome any decalcifying effect they may have. Any effects that might be attributed to a toxamin can be overcome by a variety of methods, such as the addition of substances producing a vitamin D effect or by the direct irradiation of the cereal products. On the assumption that it might be well for the general improvement of the nutrition of the people of the United States to have available cereal products which have been treated so as to have a "slightly positive effect" on calcification, instead of what might be termed a negative effect, certain vitamin D fortified cereals have appeared on the market. The present report aims to consider the evidence regarding the rationality of adding vitamin D in some form to cereals in order to overcome an anticalcifying effect supposed by some investigators to be a property of cereals.

EVIDENCE OF THE EXISTENCE OF A TOXAMIN

In 1926 Mellanby² definitely postulated the existence of a toxamin, the effects of which could be overcome by vitamin D or the toxic factor itself could be destroyed by treatment with diluted hydrochloric acid. If oatmeal was boiled with 1 per cent hydrochloric acid until the starch was hydrolyzed and the resulting mixture was then neutralized with soda the substance interfering with calcification was apparently destroyed. Several other investigators including Holst,³ Mirvish⁴ and Christiansen⁵ studied hydrochloric acid extracts of oats. Injected into rabbits a neutralized extract resulted in a fall of blood calcium, which was interpreted as evidence that the hydrochloric acid had removed a substance which might interfere with calcification. Christiansen, however, believed that the effect on blood calcium need not be attributed to any specific substance in the oat extract because dextrose and other substances had a similar effect. May Mellanby⁶ in 1929 reported that it had not been possible up to that time to show that the anticalcifying action of cereals is due to any known constituent of the diet. In 1930 Edward Mellanby⁷ reported that he had succeeded in separat-

ing the anticalcifying and the calcifying (vitamin D) factors from cereals by taking advantage of the solubility of vitamin D in petroleum ether.

None of the experiments on the concentration of the supposed decalcifying factor of cereals presents what might be considered conclusive evidence. The American workers, in contrast with some of the British workers, have generally believed that experimental rickets was produced by a disproportion of calcium and phosphorus in the diet, together with a deficiency of vitamin D, and that there was no need to suggest the existence of a hypothetical decalcifying factor to explain experimental observations. Fine⁸ in 1930 noted differences in the degree of rickets produced in rats when different cereals were used in the experimental ration, but he ascribed these differences in effect to the slight differences in vitamin D content of the various grains that he used. Careful experiments have indeed shown that there are apparently slight differences in the degree of rickets produced in experimental rats when different cereals are used in the basal diet. Green and Mellanby⁹ reported that oats produced a more severe degree of rickets than other cereals, but their diets were not strictly comparable. Steenbock, Black and Thomas,¹⁰ on the other hand, reported that the degree of rickets was greater when corn was used in the basal diet than when oats or wheat was used. These cereals differ in their content of phosphorus. By adjusting the calcium and phosphorus contents of the different diets so that the ratio of the two elements was constant, Thomas and Steenbock¹¹ in 1936 were able to observe but little difference in the degree of rickets produced in experimental animals. None of these investigations has definitely established the existence of a toxic substance in cereals or shown conclusively that this substance is present in different concentrations in different cereals.

NEWER STUDIES

More recent investigations have clarified our conception of the processes that take place in the production of experimental rickets. These investigations have also clarified our notions of the effect of the cereal component of the rickets-producing diet.

Calcium and Phosphorus Ratio.—The importance of the calcium and phosphorus ratio of the experimental diet has been recognized from the time of the pioneer investigations of McCollum and of Sherman and their collaborators. It was known for example, that the diet must contain more than two parts of calcium (Ca) to one part of phosphorus (P) in order to produce high calcium rickets in rats. The experimental rations most frequently used such as those of Steenbock and Black, McCollum, and Sherman and Pappenheimer contain about 4 parts of calcium or more to one part of phosphorus. Low-calcium or as it has sometimes been called, high-phosphorus rickets, can be produced when the amount of phosphorus in the diet is several times that of the calcium. Such diets are not used extensively in the study of rickets in rats but are customarily used in the production of rickets in puppies.

The work of Bethke¹² and of Shohl and his collaborators has led to a more precise knowledge of the significance of the calcium and phosphorus content of the diet on the degree of rickets produced in experimental animals. Shohl¹³ observed that not only is the ratio of calcium and phosphorus important but also the concentration of the two elements in the diet. In the absence of vitamin D a ratio of four parts of calcium to one part of phosphorus would produce rickets only if the concentration of the phosphorus was 0.5 per cent or more, with lower amounts of phosphorus but with the same ratio of

calcium to phosphorus, the rickets was either less severe or an essentially normal bone was produced. A striking demonstration of the importance of the concentration of phosphorus in the diet was afforded by the results obtained with Ca:P ratios of 1:1 or 2:1. These ratios have long been thought to be "optimum" for production of normal bone. But Shohl has shown that, by decreasing the amount of phosphorus, one can obtain rickets even with these "normal" ratios. The diets which Shohl used were patterned after the rickets-producing diet of Steenbock and Black, which is made up principally of yellow corn, wheat gluten, salt and calcium carbonate.

These experiments help to explain some of the observations regarding the effect of different cereals on the degree of rickets produced. Corn, wheat and oats vary greatly in their total content of phosphorus. If one varies the cereal component of the diet, the ratio of calcium and phosphorus also is altered. Recalculation of some of the experimental data in the literature shows that the substitution of one cereal for another has shifted the calcium and phosphorus ratio level sufficiently in some instances to change the diet from the normal zone to the rickets-producing zone according to Shohl's chart.

The Availability of the Phosphorus—Recent work has shown that consideration must be given also to the availability of the phosphorus of the cereal component of the rickets-producing diet. Some of the phosphorus of grains is in the form of phytin. Harris and Bunker¹⁴ found that the proportion of the total phosphorus in the form of phytin is variable and may be from 30 to 70 per cent in different samples of a single grain such as corn. Phytin appears to be poorly utilized by the human being or the rat. McCance and Widdowson¹⁵ showed in 1935 that phytin was poorly utilized by man and that such utilization as did occur was probably the result of the action of intestinal bacteria which hydrolyzes the phytin. Bruce and Callow¹⁶ in 1934 developed a method for the determination of phytin. Their experiments led them to conclude that the differences in the degree of rickets produced with different cereal mixtures could be accounted for on the basis of the amount of available phosphorus in the diet. The most recent experiments have been reported by Lowe and Steenbock.¹⁷ They emphasized that phytin could be hydrolyzed by treatment with diluted hydrochloric acid to give inorganic phosphates, an observation that may explain why some of the earlier workers obtained better bones in their experimental animals when they treated the cereals with dilute acid. Instead of destroying a hypothetical toxic factor, it is more likely that the acid treatment hydrolyzed the phytin, thus altering the ratio of calcium to available phosphorus in the diet. Lowe and Steenbock also showed that phytin was hydrolyzed to a large extent by the bacteria in the intestine of rats. However, if calcium carbonate or other calcium salts were added to the ration—and this is the usual procedure in constructing a rickets-producing diet—the phytin was not as completely hydrolyzed as it was when the calcium salts were omitted from the diet. They believed that the presence of the calcium carbonate changed the bacterial flora of the intestinal tract.

CONCLUSIONS

It may be concluded that there is no good evidence for the existence of a decalcifying factor in cereals, and that the hypothesis of the existence of such a factor is not needed to explain experimental results. Production of rickets in rats is effected by a diet which is low in vitamin D and which also has a disproportion of calcium and phosphorus. The concentration of the calcium and phosphorus in the diet is just as important as the ratio of the two in determining the degree of rickets produced. The concentration of phosphorus is determined partly by the amount of available phosphorus in the diet. Phytin phosphorus may or may not be completely available to the organism, depending on the extent to which it is hydrolyzed by intestinal bacteria. The experimental results observed and

reported in the literature may be explained on the basis of the calcium and phosphorus ratio in the diet together with a knowledge of the availability of the phosphorus. Grain products not treated with vitamin D are wholesome foods. There appears to be no necessity at the present time to irradiate cereals or to add vitamin D substances to cereal products intended for general human consumption, in order to overcome the harmful effects of a hypothetical toxin.

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COUNCIL ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION AND WILL BE LISTED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED

FRANKLIN C. BING, Secretary

- (1) SEXTON BRAND ROYAL ANNE CHERRIES, JUICE PACKED
- (2) SEXTON BRAND BLACK CHERRIES, JUICE PACKED
- (3) SEXTON BRAND PRUNE PLUMS, JUICE PACKED

Manufacturer—John Sexton & Company, Chicago

Description—(1) Canned cherries packed in juice, (2) canned black cherries, packed in juice, (3) canned prune plums, packed in juice.

Manufacture—Cherries and plums are stemmed, pressure spray washed, sorted, graded, again washed, inspected and placed in cans. The cans are automatically filled with fruit juice, exhausted, sealed and processed.

Analyses (submitted by manufacturer)—(Analyses of entire contents including liquid)

	(1)	(2)	(3)
Moisture	82.6%	81.1%	79.9%
Total solids	17.4	18.9	20.1
Ash	0.6	0.5	0.6
Fat (ether extract)	0.1	0.1	0.1
Protein (N × 6.25)	1.0	0.5	0.5
Crude fiber	0.2	0.1	0.2
Carbohydrates other than crude fiber (by difference)	15.5	17.7	18.7

Calories—(1) 0.66 per gram, 19 per ounce; (2) 0.73 per gram, 21 per ounce; (3) 0.77 per gram, 22 per ounce.

Claims of Manufacturer—For diets in which sweetened fruit is proscribed.

CEREVIM

Manufacturer—Hugh Tebault and Company, New York City

Description—A flaky mixture of cooked wheat, oats, powdered skim milk, wheat germ, yellow cornmeal, dried brewers' yeast, sodium chloride, barley and malt.

Manufacture—Formula proportions of the dry ingredients are mixed with water, cooked, dried, flaked and packed into cartons.

Analysis (submitted by manufacturer)—Moisture 37%, total solids 96.3%, ash 3.8%, fat (ether extract) 3.4%, protein (N × 6.25) 18.5%, crude fiber 1.5%, carbohydrates other than crude fiber (by difference) 69.1%, phosphorus (P) 0.510%, potassium (K) 0.486%, sulfur (S) 0.211%, calcium (Ca) 0.170%, chloride 0.164%, sodium (Na) 0.160%, magnesium (Mg) 0.141%, silicon (Si) 0.019%, iron (Fe) 0.006%, copper (Cu) 0.003%.

Calories—107 per ounce.

Vitamins—Enriched in vitamins B₁ and G, furnished by skim milk, wheat germ and dried yeast.

Claims of Manufacturer—Cerevim is a palatable, precooked cereal food, richer in protein and in calcium and phosphorus because of its skim milk content. It is also enriched in vitamins B₁ and G, furnished by skim milk, wheat germ and dried yeast.

ADVERTISING LEAFLET "WHOLE MILK FOR THE WHOLE FAMILY"

Sponsor—Irradiated Evaporated Milk Institute, Chicago

A revised leaflet which describes the nutritional properties of whole milk. Recipes, which recommend irradiated evaporated milk in cooking, are included.

SATURDAY, JULY 3, 1937

THE AMERICAN MEDICAL ASSOCIATION AND THE CARE OF THE INDI- GENT SICK

In the welter of words that poured from Atlantic City, reporting the actions of the House of Delegates to the American people, some may find difficulty in ascertaining exactly what was decided with regard to the policies of the Association on the provision of medical care. The medical profession has never failed in its ideal of medical care for all—rich and poor alike—regardless of their ability to pay. At the Cleveland session the House of Delegates adopted ten principles that should prevail in medical practice. Those principles have not been changed. The ideals of mutual responsibility between doctor and patient, unalterable opposition to commercialized, bureaucratic or state practice, and willingness to do our utmost in providing all that can be provided to the sick still remain among the accepted principles of American medicine.

Some significant incidents in the period between the annual session of 1936 and the one this year were concerned definitely with the actions taken in the House of Delegates. The American Foundation Studies in Government published its report. Attempts were made by various groups to set up cooperative medical practice in various portions of the country. In some state legislatures bills were introduced to make legal compulsory sickness insurance and cooperative practice within those states. A committee was assembled to translate the findings of the American Foundation Studies in Government into action by the American Medical Association. A group of specially selected physicians who had extended themselves in their communications to the foundation, who coincided in their views largely with the director of the foundation, who were willing to approve certain policies that seemed to grow out of the reports of the foundation, were invited, according to published reports, to attend a luncheon in the White House. Out of that luncheon, according to the same reports, came recommendations for the development of a national health policy, expansion in

preventive medicine, federal subsidies to medical schools and to voluntary hospitals, and the establishment of a federal department of health with a physician in the cabinet. In the closing session of the House of Delegates of the New York State Medical Society these propositions were put forward and adopted with modifications, most important of which were the repeated suggestions that all plans developed in various communities must be approved by the local medical society before they could be put into effect in such communities. These resolutions, adopted by the New York State Medical Society, were brought to the House of Delegates of the American Medical Association. In the hearings before the Reference Committee in the House of Delegates it became apparent that there was no warrant that the federal government could undertake to subsidize any form of medical care in any local community subject to approval of the plan by any single, self-constituted group within that community. After long hearings, the House of Delegates adopted the report of its Reference Committee to the effect that the Association had already taken action approving a federal department of health with a physician in the cabinet, that the Board of Trustees had already indicated to the federal government its desire to be of the utmost service in the development of suitable plans for the care of the indigent sick, and that the Association and the officers thereof stood ready now as in the past, on direct request, to do their utmost to aid the administration in working out such plans.

The visit of Senator James Hamilton Lewis of Illinois was a newsworthy event. He came in response to an invitation given by the House of Delegates on his own request. His message, published in full in THE JOURNAL last week, seems to indicate that the administration, or possibly legislators in Washington, propose an attempt to federalize medical practice by demanding federal licensure for physicians who care for the indigent sick, since these might be construed as wards of the federal government. The Senator stated his personal opposition to such a procedure and urged the Association to develop some means in connection with forthcoming legislation whereby the ideals of medical practice might be maintained. He brought to the Association a message which he declared had been given to him over the telephone by the President just previous to his departure from Washington, a message in which the President said, according to Senator Lewis, who claimed to quote the exact words of the President:

He hoped that you would find a way to cooperate with him in such method as you would jointly find would be to the service of the helpless and the afflicted within such province as you felt government should undertake.

The House of Delegates authorized the Board of Trustees to send to the President a suitable reply.

The problems of medical care have been during the past ten years like a seething volcano, constantly erupting great masses of fire in the form of hastily con-

cocted, dangerous schemes and plans which the medical community and the public alike had to avoid or perish. The eruptions associated with the last annual session vary, however, from those which occurred in the past. They seemed to come, although somewhat indirectly, from Washington. The reports, according to the Associated Press, evoked from the President a statement to the effect that he "did not have in mind any recommendations for setting up a system of federalized medicine." Furthermore, the end result was a direct proffer, by the House of Delegates of the American Medical Association to the United States government, of the services of the Association in working out suitable plans for the care of the indigent sick.

The action of the House of Delegates places on the Board of Trustees a tremendous responsibility, no greater, however, than that which it has conscientiously carried during the trials of the last ten years. The legislative powers of the Association, according to the Constitution, reside in the House of Delegates. The House has not indicated its acceptance of any new form of medical practice. It has, however, authorized the Board of Trustees, as its representatives, to cooperate with the government in developing the best possible care of the indigent sick, within the principles fundamental to good medical service previously established.

UTILIZATION AND RETENTION OF VITAMIN B₁ IN CHILDREN

Knowledge of the physiologic role of the vitamins has been developed largely from studies of the pathologic changes resulting in experimental animals deprived of these dietary essentials. Investigations of this type have in most instances clearly defined the minimal amount of a particular vitamin compatible with normal health and well being. Although the range of vitamin requirement has been carefully delimited in laboratory animals, relatively little accurate information is available for the human requirement. This can be partially attributed to the inadequacy of data regarding the proportion of ingested vitamin that is actually utilized by the body. The efficiency of this process may vary widely among the different vitamins, and only extended investigations will make possible an accurate evaluation of the factor of utilization. Careful balance studies are needed. The chief difficulty of the latter type of investigation is the lack of a convenient method of determining the small quantities of vitamin in the limited amount of material usually available for the assay. However, with the development of refinements in bioassay an approach is being made to the question of the actual human requirement for the vitamins.

The requirement of man for vitamin B (B₁) has been discussed in a recent monograph by Cowgill.¹ The

importance of this vitamin for normal nutrition and growth and its relation to anorexia is especially significant in early childhood. Although it is recognized that in children anorexia is most frequently the result of either a behavior characteristic or a physical defect, there is evidence that an increase above the customary vitamin B₁ intake may result in marked improvement in both appetite and weight in some infants and young children. In one large series of cases of chronic anorexia (indicated by subnormal weights and other objective signs of malnutrition) it was found that about one third of the children had no organic lesion to account for their condition.² This group responded well to a variety of dietary additions but improved so markedly when liver, beefsteak or kidney was fed that the investigator was led to conclude that the feeding of liver may be a specific stimulant to appetite. Although he did not attempt to determine just what factor was responsible for these results, it is well known that among the important dietary constituents of liver is vitamin B₁, which might account at least in part for the results obtained. This suggestion lends particular significance to attempts to determine quantitatively the utilization and retention of vitamin B₁ in children, as influenced by different levels of the vitamin intake. Results of this type of study have been recently reported³ from the Iowa Child Welfare Research Station of the University of Iowa.

Twenty-three balance studies were conducted with eight children from 4 to 7 years of age. The utilization of vitamin B₁ was determined by biologic assay of the amount of the vitamin in the food and excreta of the children receiving weighed diets. Experimental periods of three weeks' duration were employed, during which time the same foods were served each day, the amount for each child being in proportion to his height and theoretical weight. Ingestion of vitamin B₁ at three different levels was studied. The most striking result of the investigation was the definite trend toward higher retentions of vitamin B₁ accompanying higher levels of intake in the children. The data also suggest that the body is not capable of building up a significant reserve of vitamin B₁, in view of the fact that depletion rapidly occurs on low ingestion levels. This observation serves to emphasize the need for a continued, adequate supply of the vitamin. The levels of daily vitamin intake which resulted in the highest retention were found to be about 27 international units per kilogram of body weight, from six to seven times greater than the minimal requirement for preventing beriberi as determined by means of the formula suggested by Cowgill.¹

If the level of vitamin intake producing the highest retention may be considered optimal, the wide range observed between minimal and optimal requirement

would aid in explaining both the existence of vitamin B₁ deficiency among children and the beneficial results obtained by additions of vitamin B₁ to the diet. This careful quantitative balance study is timely in view of the reported manifestations of vitamin B₁ deficiencies in children.

CLIMATE

Various aspects of climate and weather in relation to general health and specific diseases have been frequently referred to in these columns.¹ The scientific interest in these matters is second only to that expressed in general conversation. A Californian, according to Chun,² is credited with the statement that, if one were to eliminate health and weather from conversation, two thirds of the nation would be tongue tied. In any case the interest aroused by this subject in scientific circles reflects the frequency with which professional advice is sought.

A recent issue of the *Journal of State Medicine*³ contains a series of three articles on the curative action of sea climate and two on wintering in England. According to Professor Kestner, people gain in health and vigor after living for some weeks at a health resort on the seashore. The principal explanation for this phenomenon, he believes, is the stimulating effect of the climate on the skin. Furthermore, the oxygen consumption is increased on the sea and in the Alps and is related in both climates to the retention of nitrogen. The stimulus of the sea also promotes secretion of the gastric juices, which in itself, he claims, is a factor tending toward increased health. Langdon-Brown feels that among other favorable factors the conditions provided on the south coast of England by the equable temperature, humidity and pine-laden breezes are admirable for chronic bronchitis and emphysema. Watson Smith states that the bracing east coast resort is more satisfactory for the hardy young or middle-aged adult. The more moist and less sunny climate of the west coast is better suited to less rugged constitutions. The sedative winter and summer climates of the south coast are more favorable for the less vigorous, catarrhal or febrile patient, especially if elderly. Similar discussions of various areas of England are included in the two papers on wintering in England. Moreover, the specific qualities of each area are described in more detail in the Official Handbook of the British Health Resorts Association for 1937.⁴ Bonacina states in the introduction to this book that a much discussed but persistently obscure subject in medical climatology is

the effect of bracing and relaxing qualities. It appears to be true, he states, even if somewhat exaggerated, that the east coast of Great Britain is more bracing than the west coast, and that fact receives appropriate emphasis.

Chun is convinced that the relation between temperature and humidity is of great practical importance. In general it may be said that moist air is depressing and enervating, while dry air is stimulating, also that cold air is tonic, while warm air is relaxing. Certain combinations of these conditions must therefore be considered in choosing satisfactory environments for different states of health.

Without actually moving to a place where particularly desirable climatic conditions exist, it is possible now to modify to some extent the external environment by so-called air conditioning. Such measures, in fact, have become so important that a special article on the subject has appeared in a recent issue of *THE JOURNAL*.⁵ Modifications in humidity and temperature to conform with optimal conditions now frequently can be made. There is naturally a great difference in the scientific basis of the studies of weather and its relation to health and disease. Certainly the interest now displayed in the subject leads to the hope that more exact knowledge is fomenting.

Current Comment

HEART DISEASE RACKET

In the Organization Section in this issue of *THE JOURNAL* appears a preliminary report of an extensive insurance fraud investigated by the United States Public Health Service. The author of the article obtained the material while serving in the capacity of medical adviser to the office of the United States attorney. In all the annals of criminal ingenuity with a medical tinge there has seldom been a more cold blooded, heartless or vicious scheme than the one now described. The manner in which patients who permitted themselves to be inveigled into the racket were first physically exhausted and then perhaps permanently damaged by the use of drugs, the manner in which competent, ethical physicians, without even a hint of suspicion, were drawn into the scheme so that their prestige and their names might be abused for the benefit of the swindlers, and the manner in which the most modern scientific methods of diagnosis were employed in order to give the appearance of scientific authenticity to the reports—all these are unique in criminal annals. The investigation represents a fine cooperative effort between the medical and legal authorities involved. As the fight against crime becomes more complex and intricate, the need for further cooperation becomes more manifest. As crime becomes more and more scientific, physicians will have to be more and more on their guard against those who would abuse their confidence for personal financial gain.

PROCEEDINGS OF THE ATLANTIC CITY SESSION

MINUTES OF THE EIGHTY EIGHTH ANNUAL SESSION OF THE AMERICAN MEDICAL ASSOCIATION, HELD AT ATLANTIC CITY, JUNE 7-11, 1937

(Concluded from page 2228, volume 108)

MINUTES OF THE SECTIONS

SECTION ON PRACTICE OF MEDICINE

WEDNESDAY, JUNE 9—MORNING

The meeting was called to order at 9 o'clock by the chairman, Dr John H Musser, New Orleans

Drs R Earle Glendy and Paul D White, Boston, presented a paper on "Coronary Disease in Youth" Discussed by Drs H M Marvin, New Haven, Conn, W D Stroud, Philadelphia, and Paul D White, Boston

Dr Fred M Smith, Iowa City, read a paper on "Treatment of Acute Left Ventricular Failure" Discussed by Drs N C Gilbert, Chicago, R D Book, Corning, Ohio, and Fred M Smith, Iowa City

Dr Walter L Bierring, Past President of the American Medical Association, introduced Dr Joseph A Capps, Chicago, who read the Frank Billings lecture, entitled "The Cause of Pleural Shock Air Embolism or Pleural Reflex"

Dr John P Peters, New Haven, Conn, read a paper on "The Nature of Pregnane Toxemia"

Drs J Edwin Wood Jr and Harold G Nix, University, Va, presented a paper on "Pregnancy and Hypertension"

These two papers were discussed by Drs Joseph M Hayman Jr, Cleveland, Soma Weiss, Boston, John P Peters, New Haven, Conn, and J Edwin Wood Jr, University, Va

Drs Perrin H Long and Eleanor A Bliss, Baltimore, presented a paper on "The Use of Sulfanilamide in the Treatment of Beta-Hemolytic Streptococcus Infections" Discussed by Drs Chester S Keefer, Boston, Francis F Schwentker, Baltimore, John H Musser, New Orleans, and Perrin H Long, Baltimore

THURSDAY, JUNE 10—MORNING

It was moved by Dr Charles H Cocke, Asheville, N C, and seconded by Dr Walter E Vest, Huntington, W Va, that consent be given by the section for the reading of the following papers, the understanding being that they were unofficial and did not create a precedent "Bronchial Spirometry," by Dr H C Jacobus, professor of medicine, Karolinska Institute, Stockholm, Sweden, and "The Comparative Value of Purine Derivatives in the Treatment of Angina Pectoris," by Drs Norton G Brown and J C F Riseman, Boston These papers were added because of the fact that Dr Gustav Nylin was unable to be present to read his paper and Dr William Charles White was unable to attend the meeting because of illness The motion was put to a vote and carried

Dr Thomas Francis Jr, New York, read a paper on "Studies with Human Influenza Virus During the Influenza Epidemic of 1936-1937" Discussed by Drs Francis G Blake, New Haven, Conn, and Thomas Francis Jr, New York

Drs Morton G Brown and J E F Riseman, Boston, presented a paper on "The Comparative Value of Purine Derivatives in the Treatment of Angina Pectoris"

Dr John H Musser, New Orleans, read the chairman's address, entitled "The Future of Internal Medicine"

Dr H C Jacobus, Stockholm, Sweden, read a paper on "Bronchial Spirometry"

Dr Esmond R Long, Philadelphia, read the paper of Dr William Charles White, Washington, D C, on "Parasitism of the Tubercle Bacillus"

Dr J Burns Amberson, New York, read a paper on "The Lasting Cure of Early Pulmonary Tuberculosis"

Dr H W Hetherington, Philadelphia, read a paper on "Problems in the Diagnosis and Management of Latent, Suspected and Early Clinical Tuberculosis"

The papers of Drs White Amberson and Hetherington were discussed by Drs Bruce H Douglas, Detroit Charles H Cocke Asheville, N C Francis M Pottenger Jr, Monrovia, Calif, S A Savitz Philadelphia, Emil Bogen, Olive View Calif, Samuel Friedman, New York, and Esmond R Long, Philadelphia

FRIDAY, JUNE 11—MORNING

The following officers were elected chairman, Francis G Blake, New Haven, Conn, vice chairman, Dr T H Coffen, Portland, Ore, secretary Dr Fred M Smith Iowa City (three years), executive committee Dr John H Musser, New Orleans, Dr William J Kerr, San Francisco, Dr Francis G Blake, New Haven, Conn, delegate, J E Paullin, Atlanta, Ga (two years), alternate, Dr Ernest E Irons, Chicago, representative on Board of Internal Medicine, Dr Reginald Fitz Boston (three years)

Drs L B Laplace and J T Nicholson, Philadelphia, presented a paper on "Prolonged Recumbency as a Contributory Cause of Death in Elderly Persons" Discussed by Drs Robert Wilson, Charleston S C, Clarence L Andrews, Atlantic City, N J, De Forest P Willard, Philadelphia, Norman E Freeman, Philadelphia, J E Hirsh, Birmingham Ala, and L B Laplace, Philadelphia

Dr C P Rhoads, New York, read a paper on "Refractory Anemia Its Diagnosis and Treatment" Discussed by Drs George R Minot, Boston, Randolph West New York, Hyman I Goldstein, Camden, N J, and C P Rhoads, New York

Dr John H Talbott, Boston, read a paper on "Gout" Discussed by Drs William S Ladd, New York, and John H Talbott, Boston

Drs Alexander B Gutman and W Barclay Parsons, New York, presented a paper on "Hyperparathyroidism Simulating Paget's Disease" Discussed by Drs Walter Bauer, Boston, and Alexander B Gutman, New York

Dr A R Barnes, Rochester, Minn, read a paper on "Pulmonary Embolism" Discussed by Drs William J Kerr, San Francisco, O H Perry Pepper, Philadelphia, David Ward Scanlan Atlantic City, N J and A R Barnes, Rochester, Minn

Dr Harold J Jeghers, Boston, read a paper on "The Degree and Prevalence of Vitamin A Deficiency in Adults, with a Note on Its Experimental Productions in Human Beings" Discussed by Drs M A Blankenhorn, Cincinnati, John B Youmans, Nashville, Tenn, M G Wohl, Philadelphia and Harold J Jeghers Boston

SECTION ON SURGERY, GENERAL AND ABDOMINAL

WEDNESDAY, JUNE 9—AFTERNOON

The meeting was called to order at 2 05 by the vice chairman, Dr Alton Ochsner, New Orleans

Dr Chalmers H Moore, Birmingham Ala, read a paper on "The Treatment of Cramocerebral Trauma" Discussed by Drs Walter E Dandy, Baltimore, and R Glen Spurling Louisville, Ky

Drs Walter G Maddock Frederick A Collier and Syvend Petersen, Ann Arbor, Mich, presented a paper on "Blood

Chemistry Studies in Thyroid Crisis" Discussed by Drs George Crile Jr, New York, John Paul North, Philadelphia, and Willard Bartlett Jr, St Louis

Dr Robert S Dinsmore, Cleveland, read the chairman's address, entitled "Prevention of Morbidity in Thyroid Surgery"

Dr Arthur M Shipley, Baltimore, read a paper on "Present Day Status of Surgery of the Heart and Pericardium" Discussed by Drs Claude S Beck, Cleveland, and Isaac Alexander Bigger, Richmond, Va

Dr Edward J Donovan, New York, read a paper on "Congenital Hypertrophic Pyloric Stenosis in Infancy" Discussed by Drs William E Ladd, Boston Alfred Jerome Brown, Omaha, John J Gilbride, Philadelphia, Aldred A Strauss, Chicago, and Misch Casper, Louisville, Ky

Drs Samuel F Marshall and Everett D Kiefer, Boston, presented a paper on "Partial Gastrectomy for Gastric and Duodenal Ulcer" Discussed by Drs Everett D Kiefer, Boston, and Richard Lewisohn, New York

THURSDAY, JUNE 10—AFTERNOON

Dr John S Lundv, Rochester, Minn, read a paper on "Recent Advances in Anesthesia" Discussed by Drs Henry S Ruth, Philadelphia, and Ralph M Tovell, Hartford, Conn

Dr William L Estes Jr, Bethlehem, Pa, read a paper on "Partial Cholecystectomy in Acute Suppurative Cholecystitis" Discussed by Drs William D Haggard, Nashville, Tenn, Donald Guthrie, Savre, Pa and Moses Behrend, Philadelphia

Drs Robert Zollinger, Charles D Branch and Orville T Bailey, Boston, presented a paper on "Instrumental Dilatation of the Ampulla of Vater Experimental and Clinical Observations" Discussed by Drs Waltman Walters, Rochester, Minn, and Arthur W Allen, Boston

Dr Robert Lee Payne, Norfolk, Va, read a paper on "Post-operative Care of Bile Tract Surgery" Discussed by Drs Edwin P Lehman, University, Va Harold L Foss, Danville, Pa Frank K Boland, Atlanta, Ga, Willard Bartlett Jr, St Louis and Peter B Salatch, New Orleans

Drs Otto Carl Pickhardt and Henry Aaron Rafsky, New York, presented a paper on "Diagnostic and Therapeutic Problems Presented by Lesions of Right Lower Quadrant" Discussed by Drs Ernest H Gaither, Baltimore, and Frank H Lahav, Boston

FRIDAY, JUNE 11—AFTERNOON

The following officers were elected chairman, Dr Hugh H Trout, Roanoke, Va, vice chairman, Dr Frederick L Reichert, San Francisco secretary, Dr Henry W Cave, New York, delegate to House of Delegates, Dr Fred W Rankin, Lexington, Ky, alternate, Dr Thomas M Joyce, Portland, Ore nominee to Board of Governors of American College of Surgeons Dr Grover C Penberthy, Detroit members elected to Board of Anesthesiology, Drs Henry S Ruth, Philadelphia, six years H Boyd Stewart, Tulsa, Okla, four years, Ralph M Tovell, Hartford Conn, two years

Drs Edward M Hanrahan Jr, Maxwell M Wintrobe and Caroline B Thomas, Baltimore, presented a paper on "Purpura Haemorrhagica with Special Reference to Its Course and Treatment" Discussed by Drs Allen O Whipple, New York and George R Minot, Boston

Dr Arthur W Allen, Boston, read a paper on "Right Colectomy for Malignant Disease A Discussion of the Mortality Associated with Various Operative Procedures" Discussed by Drs Fred W Rankin, Lexington Ky, and Harvey B Stone, Baltimore

Dr William Crawford White, New York, read a paper on "Present Views Regarding Irradiation as an Aid to Surgery in Cancer of the Breast" Discussed by Drs Frank E Adair, New York, Ernest Daland, Boston, and George M Dorrance, Philadelphia

Drs Loyal Davis and Leon I Aries, Chicago, presented a paper on "The Prevention of Postoperative Adhesions About Nerve and Tendon Sutures" Discussed by Dr Herbert L Johnson, Boston

Dr Harvey B Stone, Baltimore, read a paper on "Rectal Symptoms from the General Surgeon's Point of View" Discussed by Drs Curtice Rosser, Dallas, Texas and Frank C Coleman, New York

Dr C Latimer Callander, San Francisco, read a paper on "Further Experience with a New Tendoplastic Amputation Through the Femur at the Knee" Discussed by Dr Joseph S McGinness, San Francisco

SECTION ON OBSTETRICS, GYNECOLOGY AND ABDOMINAL SURGERY

WEDNESDAY, JUNE 9—MORNING

The meeting was called to order at 9 o'clock by the chairman, Dr M Pierce Rucker, Richmond, Va

Dr Virgil S Counseller, Rochester, Minn, read a paper on "The Surgical Treatment of Uterine Myomas" Discussed by Drs Thomas S Cullen, Baltimore, Louis E Phaneuf, Boston, and Henry Schmitz, Chicago

Dr A Louis Dippel, Baltimore, read a paper on "The Diagonal Conjugate versus X-Ray Pelvimetry" Discussed by Drs J Bay Jacobs, Washington, D C, Edward L Cornell, Chicago, and W T McConnell, Louisville, Ky

Drs Norman F Miller and Russell L Malcolm, Ann Arbor, Mich, presented a paper on "An Evaluation of Common Lesions of the Cervix" Discussed by Drs Floyd E Keene, Philadelphia, Lawrence R Wharton, Baltimore, Jean Paul Pratt, Detroit, C F Fluhmann, San Francisco, and Karl H Martzloff, Portland, Ore

Drs Harvey B Matthews and Maurice G Der Brucke, Brooklyn, presented a paper on "Normal Expectancy in the Extremely Obese Pregnant Woman" Discussed by Drs Nicholson J Eastman, Baltimore, and Jennings C Litzberg, Minneapolis

With the unanimous consent of the section, Dr K de Snoo, Utrecht, Holland, presented a paper by title on "The Treatment of Repeated Abortion on Repeated Antenatal and Postnatal Deaths" At the request of the section officers, Dr K de Snoo then presented a 16 mm motion picture film on "Comparative Physiology of Labor"

THURSDAY, JUNE 10—MORNING

The following papers were read as a symposium on "The Clinical Use of Endocrine Products"

Drs Robert T Frank, Morris A Goldberger and U J Salmon, New York "Oligomenorrhea and Amenorrhea Causation and Treatment"

Drs John C Burch, G S McClellan, John W Simpson, Claud Johnson and E T Ellison, Nashville, Tenn "The Treatment of Glandular Cystic Hyperplasia of the Endometrium by Endocrine Products"

Dr Jennings C Litzberg, Minneapolis "The Endocrines in Relation to Sterility and Abortion"

Dr Jean Paul Pratt, Detroit "The Endocrine Treatment of Menopausal Phenomena"

Dr Robert M Lewis, New Haven, Conn "Endocrine Treatment of Vaginitis of Children and Women After the Menopause"

These five papers were discussed by Drs Emil Novak, Baltimore, Elmer L Sevringhaus, Madison, Wis, E C Hamblen, Durham, N C, Fred H Falls, Chicago, Samuel S Rosenfeld, New York, August A Werner, St Louis, Charles W Dunn, Philadelphia, Jacob Hoffman, Philadelphia Misch Casper, Louisville, Ky, Cecil Striker, Cincinnati, and Peter B Salatch, New Orleans

Dr Arthur H Curtis, Chicago who was named to the Executive Committee in place of Dr Lyle G McNeile, Los Angeles, reported for the Executive Committee relative to the nominations for the election to take place on Friday morning

Dr M Pierce Rucker, Richmond, Va, read the chairman's address, entitled "The Treatment of Eclampsia"

The Talking Motion Picture "The Birth of a Baby" was presented

FRIDAY, JUNE 11—MORNING

The following officers were elected chairman Dr Everett D Plass, Iowa City, vice chairman, Dr Harvey B Matthews, Brooklyn, secretary, Dr Norman F Miller, Ann Arbor, Mich nominee to Board of Governors of the American College of Surgeons Dr Jean Paul Pratt, Detroit Committee on Mater-

nal Welfare, Drs James Raglin Miller, Hartford, Conn, Robert D Mussey, Rochester, Minn, and James R McCord, Atlanta, Ga

Dr H Close Hesseltine Chicago, read a paper on "Evaluation by Controlled Series of Vaginal Trichomoniasis Therapies" Discussed by Dr Abraham C Rakoff, Philadelphia

Dr Abraham I Lash, Chicago, read a paper on "Further Studies of the Clinical Use of the Concentrated (Hemolytic) Streptococcus Antitoxic Serum in Puerperal Fever"

Drs George Gray Ward and Nelson B Sackett, New York, presented a paper on "Results of Radiation Therapy for Carcinoma of the Uterus at the Woman's Hospital, New York City Series 1919-1932" Discussed by Drs Mary Cutler, Chicago, Rieva Rosh, New York, and Nelson B Sackett, New York

Drs Harris J Timmerman and Magnus P Urnes, Chicago, presented a paper on "Breech Delivery A Comparative Study of Local and General Anesthesia" Discussed by Dr Joseph B DeLee, Chicago

Dr Nicholas M Alter, Jersey City, N J, read a paper on "Hydatidiform Mole and Chorionepithelioma Pathologic Studies" Discussed by Dr William R Nicholson, Philadelphia

Drs John Huberman, Newark, N J, H H Israeloff, Irvington, N J, and Ben Hymowitz, Newark, N J, presented a paper on "The Use of the Anterior Pituitary-like Principle as an Intradermal Pregnancy Test Further Observations"

SECTION ON OPHTHALMOLOGY

WEDNESDAY, JUNE 9—AFTERNOON

The meeting was called to order at 2 o'clock by the chairman, Dr William L Benedict, Rochester, Minn

Dr Arthur J Bedell, Albany, N Y, presented to the section a twenty minute, a ten minute and a five minute sand glass from Mr Leslie Paton, London, England

The chairman called for an executive session to consider a resolution

It was moved by Dr Arthur J Bedell, Albany, N Y, duly seconded and carried, that the following resolution be presented to the House of Delegates

WHEREAS The Federal Social Security Act in Title Ten has placed on the Social Security Board the responsibility of entering into cooperative arrangements with the various states for the purpose of aiding those states in granting financial assistance to needy blind individuals and has ruled that individuals in the various states applying for blind assistance must be examined by an ophthalmologist or a doctor of medicine skilled in the diseases of the eye

WHEREAS The Social Security Board has advised the official state agencies that have the responsibility of administering this aid in those states to employ a supervising ophthalmologist who will have general supervision over the medical determination of blindness within the state therefore be it

Resolved That the Section on Ophthalmology of the American Medical Association approves the action of the Social Security Board in requiring that applicants for blind assistance within the various states be examined by a regularly licensed and registered doctor of medicine skilled in diseases of the eye or by an ophthalmologist as such a procedure will serve to secure a fuller knowledge as to the causes of blindness within the United States and be it further

Resolved That the Section on Ophthalmology of the American Medical Association goes on record as approving the suggestion of the Social Security Board that the official agency in the state or territory charged with the responsibility of administering blind assistance employ a supervising ophthalmologist whose duty will be the general supervision of the medical determination of blindness of those needy individuals applying for blind assistance be it further

Resolved That the delegate from the Section on Ophthalmology of the American Medical Association be and is hereby instructed to present these resolutions to the House of Delegates

The executive session was terminated on motion duly seconded and carried

Dr William L Benedict, Rochester, Minn, read the chairman's address, entitled "The Pathology of Angioid Streaks in the Fundus Oculi"

Dr Walter R Parker, Detroit, read a paper on "Ophthalmic Education"

Dr Harry S Gradle, Chicago, and Dr Walter De Francois, Harrisburg, Ill, presented a paper on "The Visual Ravages of Trachoma" Discussed by Dr C E Rice, Washington, D C

Drs Grady E Clay and J M Baird, Atlanta Ga presented a paper on "An Unclassified Type of Optic Neuritis" Discussed by Drs E L Goar, Houston, Texas, Walter I Lillie, Philadelphia, and J M Baird, Atlanta, Ga

Drs Conrad Berens and Jacob A Goldberg New York, presented a paper on "Syphilis in Relation to the Prevention of Blindness" Discussed by Drs E V L Brown, Chicago, John Green, St Louis, Louis Lehrfeld, Philadelphia, Mr Lewis H Carris, New York, National Association for the Prevention of Blindness, and Dr Conrad Berens, New York

Dr Leo L Maver, Chicago, read a paper on "Tryparsamide Therapy of Neurosyphilis and Optic Nerve Atrophy" Discussed by Drs Frederick C Cordes, San Francisco, Walter I Lillie, Philadelphia, and Leo L Mayer, Chicago

Drs Norman P Scala, Washington, D C, and Ernest A Spiegel, Philadelphia presented a paper on "Ocular Disturbances in Lesions of the Mesencephalic Central Gray Matter" Discussed by Drs Clifford B Walker, Los Angeles, Walter B Lancaster, Boston, and Norman P Scala Washington, D C

THURSDAY JUNE 9—AFTERNOON

Dr F Herbert Haessler, Milwaukee, read a paper on 'The Near Reaction of the Pupil in the Dark A Quantitative Study' Discussed by Drs Francis H Adler Philadelphia, Frederick H Verhoeff, Boston, and F Herbert Haessler, Milwaukee

Dr David G Cogan Boston, read a paper on "The Automatic Nervous System and Accommodation" Discussed by Drs William H Luedde, St Louis, Alfred Bielschowsky, Hanover, N H S Judd Beach, Portland Maine, and David G Cogan Boston

Dr Edward Jackson, Denver, read a paper on "Late Results of Cataract Extraction" Discussed by Drs Allen Greenwood, Boston, Edward C Ellett, Memphis, Tenn, and Edward Jackson, Denver

Dr Robert E Moran Washington, D C, read a paper on "An Explanation of Exophthalmos and Enophthalmos with Surgical Correction" Discussed by Drs Albert D Ruedemann, Cleveland Frederick H Verhoeff Boston, Edmund B Spaeth, Philadelphia, Clifford B Walker, Los Angeles and Robert E Moran, Washington, D C

At the Demonstration Session the following were shown

Dr S Judd Beach, Portland Maine, presented a demonstration of statistical analysis of refraction case reports

Dr Conrad Berens, New York, presented 1 A series of stereoscopic cards 2 Visual acuity chart for amblyopic children and adults

Dr Clifford B Walker, Los Angeles, presented some new equipment in treatment of detachment of the retina

Dr George P Gubor, Chicago, presented a classification of concomitant strabismus

Dr Harry S Gradle Chicago, presented a device for adding an extra cell to the battery handle of the Bausch and Lomb ophthalmoscope

Dr John Green, St Louis presented a new caliper

Dr Parker Heath, Detroit, presented an anterior chamber irrigator

FRIDAY, JUNE 11—AFTERNOON

Executive Session

Dr Albert C Snell, Rochester, N Y, presented the report of the Committee on Compensation Tables and moved that the committee be discontinued as the majority of the work had now been accomplished The motion was seconded and carried

Dr Snell also read a preliminary report of the Special Committee on Visual Standards for Licensure to Operate Motor Vehicles, a committee made up of Dr Nelson M Black, Miami Fla, Dr Harry S Gradle, Chicago, and Dr Albert C Snell Rochester, N Y It was moved that the report be placed on file, that a copy be sent to the committee of the American Medical Association on the same subject, that the committee be continued and that it cooperate with the other committee

Dr Charles A Bahn, New Orleans, read the report of the American Committee (Joint) on Optics and Visual Physiology in the absence of the chairman, Dr Edward Jackson The report was accepted and referred to the executive committee

The report of the Committee on the Knapp Testimonial Fund was presented by Dr Parker Heath, Detroit. The report was accepted and placed on file.

For the Committee on Awarding the Knapp Medal, Dr Frederick H Verhoeff, Boston, reported that no award would be made this year.

The report of the Committee on the American Board of Ophthalmology was read by Dr Edward C Ellett, Memphis, Tenn. The report was accepted and placed on file.

Dr Parker Heath, Detroit, read the report of the Committee on Museum of Ophthalmic History, recommending that the committee be discharged and a new committee formed. The report and recommendation were accepted.

Dr John Green, St Louis, read the report of the Committee from the Section to Cooperate with the National Committee for the Prevention of Blindness. It was moved by Dr Harry S Gradle, Chicago, that the committee be instructed to make an analysis of the statistical tables of the cause of blindness as shown here and be prepared to report to this section at the next session. The motion was seconded by Dr Arthur J Bedell, Albany, N Y, and carried.

Dr Georgiana Dvorak Theobald, Oak Park, Ill., read the report of the Committee on Scientific Exhibit from the Section. The report was accepted and a vote of thanks extended the committee.

Dr Arthur J Bedell, Albany, N Y, reported as section delegate to the House of Delegates.

Dr Parker Heath, Detroit, read the report of the Committee on Ophthalmic Standards. The report was accepted and placed on file.

Dr Parker Heath, Detroit, read the report of the Committee on National Museum of Ophthalmic Pathology (Joint). The report was accepted.

The following officers were elected: chairman, Dr Parker Heath, Detroit; vice chairman, Dr A Ray Irvine, Los Angeles; secretary, Dr Derrick T Vail Jr, Cincinnati; delegate, Dr Arthur J Bedell, Albany, N Y; alternate, Dr Lawrence T Post, St Louis.

Dr Daniel B Kirby, New York, was appointed to fill a vacancy on the American Board of Ophthalmology.

Dr Sanford R Gifford, Chicago, was appointed to fill a vacancy on the American Committee (Joint) on Optics and Visual Physiology.

Dr Georgiana Dvorak Theobald, Oak Park, Ill., chairman, Dr Dohrmann K Pischel, San Francisco, and Dr Derrick T Vail Jr, Cincinnati, were appointed to constitute the Committee on Scientific Exhibit from the Section.

Dr William Henry Luedde, St Louis, chairman, Dr Adolph O Pfingst, Louisville, Ky, and Dr John W Burke, Washington, D C, were appointed to constitute the Committee to Cooperate with the National Society for the Prevention of Blindness.

Dr Albert C Snell, Rochester, N Y, chairman, and Dr Harry S Gradle, Chicago, were appointed to constitute the Committee on Compensation and Economics.

Dr Burton Chance, Philadelphia, chairman, Dr Arnold Knapp, New York, Dr Edward Jackson, Denver, Dr J W Jervey, Greenville, S C, and Dr Hans Barkan, San Francisco, were appointed to constitute the Committee on Ophthalmic History.

Dr Arnold Knapp, New York, Dr A N B Lemoine, Kansas City, Mo, and Dr Edwin M Neher, Salt Lake City, were appointed to constitute the Knapp Medal Award Committee.

Scientific Session

Dr Benjamin Rones, Washington, D C, read a paper on "Formation of Drusen of the Lamna Vitrea." Discussed by Drs Frederick H Verhoeff, Boston, Arthur J Bedell, Albany, N Y, and Benjamin Rones, Washington D C.

Dr Edmund B Spaeth, Philadelphia, read a paper on "Blepharoptosis." Discussed by Drs Ferris Smith, Grand Rapids, Mich., Daniel B Kirby, New York, and Edmund B Spaeth, Philadelphia.

Dr Walter F Duggan, New York, read a paper on "Treatment of Tobacco Amblyopia with Vasodilators."

Dr Frank D Carroll, New York, read a paper on "The Importance of Diet in the Etiology and Treatment of Tobacco Alcohol Amblyopia."

These two papers were discussed by Drs Lawrence T Post, St Louis, Arthur M Yudin, New Haven, Conn., Walter F Duggan, New York, and Frank D Carroll, New York.

Dr Walter H Fink, Minneapolis, read a paper on "The Dominant Eye: Its Clinical Significance." Discussed by Drs Derrick T Vail Jr, Cincinnati, and Walter H Fink, Minneapolis.

SECTION ON LARYNGOLOGY, OTOTOLOGY AND RHINOLOGY

WEDNESDAY, JUNE 9—MORNING

The meeting was called to order at 9 o'clock by the chairman, Dr Robert F Ridpath, Philadelphia.

William Gershom Downs, New York, and Walter George Urban, Pittsburgh, were nominated for Associate Fellowship.

Dr Thomas E Carmody, Denver, read a paper on "Osteomyelitis of the Jaws." Discussed by Drs V H Kazanjian, Boston, Robert H Ivy, Philadelphia, and Thomas E Carmody, Denver.

Dr Claude C Coleman, Richmond, Va., read a paper on "Fracture of the Skull Involving the Paranasal Sinuses and Mastoid." Discussed by Drs Francis C Grant, Philadelphia, Wells P Eagleton, Newark, N J, and Claude C Coleman, Richmond, Va.

Dr Frank H Lahey, Boston, read a paper on "The Management of Pulsion Esophageal Diverticulum Based on an Operative Experience with Seventy Cases and a Follow-Up Study of Forty-Five Cases." Discussed by Drs Stuart W Harrington, Rochester, Minn., Thomas A Shallow, Philadelphia, W Wayne Babcock, Philadelphia, and Frank H Lahey, Boston.

Dr Edmund Prince Fowler, New York, read a paper on "Measuring the Sensation of Loudness: A New Approach to the Physiology of Hearing and the Functional and Differential Diagnostic Tests." Discussed by Drs Walter Hughson, Abington, Pa., Douglas Macfarlan, Philadelphia, Horace Newhart, Minneapolis, Frederick T Hill, Waterville, Maine, and Edmund Prince Fowler, New York.

Dr Joseph L Goldman, New York, read a paper on "Prophylactic Vaccination Against Intracranial Complications Following Pneumococcus Type III Mastoiditis." Discussed by Drs Russell L Cecil, New York, W E Grove, Milwaukee, Isidore Friesner, New York, and Joseph L Goldman, New York.

THURSDAY, JUNE 10—MORNING

Dr Robert F Ridpath, Philadelphia, read the chairman's address, entitled "A Plea for a Better Understanding Between the Laryngologist and the Vocal Teacher."

Dr Burt R Shurly, Detroit, read a paper on "Otolaryngology in Relation to General Medicine." Discussed by Drs Frank R Spencer, Boulder, Colo., W P Wherry, Omaha, Claude P Brown, Philadelphia, Charles Brown, Philadelphia, and Burt R Shurly, Detroit.

Drs Isidore Friesner and J G Druss, New York, presented a paper on "Critique of the Present Treatment of Conducting Mechanism Deafness." Discussed by Drs Edward H Campbell, Philadelphia, John Randolph Page, New York, and Isidore Friesner, New York.

Dr Robin Harris, Jackson, Miss., read a paper on "A Comment on the Treatment of Chronic Purulent Otitis Media." Discussed by Drs Samuel J Kopetzky, New York, and Benjamin H Shuster, Philadelphia.

Drs Matthew S Ersner and David Myers, Philadelphia, presented a paper on "Treatment of Lateral Sinus Thrombosis Without Ligation of the Internal Jugular Vein." Discussed by Drs H Marshall Taylor, Jacksonville, Fla., Marvin Fisher Jones, New York, Philip E Meltzer, Boston, Isidore Friesner, New York, J I Kemler, Baltimore, and Matthew S Ersner, Philadelphia.

Dr E G Gill, Roanoke, Va., read a paper on "The Medical Treatment of Blood Stream Infection with Special Reference to Immunized Blood Transfusions." Discussed by Drs John A Kolmer, Philadelphia, James A Babbitt, Philadelphia, Earl Le Roy Wood, Newark, N J, and E G Gill, Roanoke, Va.

FRIDAY, JUNE 11—MORNING

Dr Chevalier Jackson, Philadelphia, presented the report of the Committee on Live Legislation. The report was accepted.

Dr John J Shea, Memphis, Tenn, reported for the American Board on Otolaryngology that it had held thirty-three examinations, in which 2,582 men had been certificated by the board. The last examination was held Monday and Tuesday June 7 and 8, in Philadelphia, at which time ninety-four candidates were examined.

The following officers were elected: chairman, Gordon B New, Rochester, Minn; vice chairman, C Coulter Charlton, Atlantic City, N J; secretary, Leroy A Schall, Boston, delegate, Burt R Shurk, Detroit, alternate, Gordon F Harkness, Davenport, Iowa, executive committee: Ralph A Genton, Portland, Ore, Robert F Ridpath, Philadelphia, Gordon B New, Rochester, Minn, Board of Otolaryngology: Joseph C Beck, Chicago, and John J Shea, Memphis, Tenn.

Dr C M Anderson, Rochester, Minn, read a paper on "Congenital Occlusion of the Posterior Choana." Discussed by Drs J P Schreffer, Philadelphia, Harry P Schenck, Philadelphia, R C Grove, New York, Gordon B New, Rochester, Minn, and C M Anderson, Rochester, Minn.

Dr Royal Reynolds, Washington, D C, read a paper on "Foreign Bodies in the Food and Air Passages: Their Early and Late Effects." Discussed by Drs Chevalier Jackson, Philadelphia, and Herman J Moersch, Rochester, Minn.

Dr Gabriel Tucker, Philadelphia, read a paper on "Tumors of the True Vocal Cords: Malignant and Benign." Discussed by Drs Henry B Orton, Newark, N J, Gordon B New, Rochester, Minn, and Gabriel Tucker, Philadelphia.

Dr Leroy A Schall, Boston, read a paper on "Exophthalmos Complicating Irradiation." Discussed by Drs Algernon B Reese, New York, Joseph C Beck, Chicago, and Leroy A Schall, Boston.

Dr Joshua C Drooker, Boston, read a paper on "Triple Primary Carcinoma in Otolaryngology." Discussed by Drs Frank W Konzelmann, Philadelphia, Louis H Clerf, Philadelphia, Leroy A Schall, Boston, Harris P Moslier, Boston, and Joshua C Drooker, Boston.

SECTION ON PEDIATRICS

WEDNESDAY, JUNE 9—AFTERNOON

The meeting was called to order at 2:05 by the chairman, Dr Ralph M Tyson, Philadelphia.

Dr Ralph M Tyson, Philadelphia, read the chairman's address, entitled "Certain Significant Aspects of Childhood Tuberculosis."

Dr William E Chamberlain, Philadelphia, read a paper on "Clinical Radiology in Pediatrics."

Dr Lewis Webb Hill, Boston, read a paper on "The Dietetic Treatment of Eczema in Early Infancy." Discussed by Drs Ralph Bowen, Oklahoma City, T Wood Clarke, Utica, N Y, Bret Ratner, New York, George Pness, Los Angeles, and Lewis Webb Hill, Boston.

The chairman appointed Drs Edgar P Copeland, Washington, D C, Edward Shaw, San Francisco, and Walter Stewart, Atlantic City, as a resolutions committee.

Dr Horace Newhart, Minneapolis, read a paper on "The Early Detection and Treatment of Hearing Defects in Children." Discussed by Drs Austin A Hayden, Chicago, Leo S Friedman, Cincinnati, and Horace Newhart, Minneapolis.

Drs Frederic W Schlutz and J L Collier, Chicago, presented a paper on "The Treatment of Nephrosis in the Young Child." Discussed by Drs A Graeme Mitchell, Cincinnati, and Frederic W Schlutz, Chicago.

Dr Clifford D Sweet, Oakland, Calif, read a paper on "The Teaching of Body Mechanics in Pediatric Practice." Discussed by Drs Lloyd T Brown, Boston, Brewster C Doust, Syracuse, N Y, Clifford D Sweet, Oakland, Calif, and Winthrop M Phelps, Baltimore.

THURSDAY, JUNE 10—AFTERNOON

Dr Louis W Sauer, Evanston, Ill, read a paper on "Municipal Control of Whooping Cough." Discussed by Drs LeRoy D Fothergill, Boston, and Charles Gilmore Kerley, New York.

Dr William H Park, New York, read a paper on "A Comparison Between the Use of Diphtheria Precipitated Toxoid and the Fluid Toxoid as a Preventive." Discussed by Drs M Bernard Brahdry, Mount Vernon, N Y, Julius Blum, New York, May Schroder, New York, and William H Park, New York.

Drs Joseph Stokes Jr, Aims C McGuinness and Paul H Langner Jr, Philadelphia, presented a paper on "Immunization with the Active Virus of Human Influenza: A Two Year Study." Discussed by Drs Thomas Francis Jr, New York, Joseph Golomb, New York, and Joseph Stoles Jr, Philadelphia.

Dr John A Toomey, Cleveland, read a paper on "Active and Passive Immunity in Poliomyelitis." Discussed by Drs Joseph Yampolsky, Atlanta, John Fitch Landon, New York, Paul H Harmon, Chicago, William H Park, New York, Benjamin Kramer, Brooklyn, and John A Toomey, Cleveland.

Dr Charles F McKhann, Boston, read a paper on "The Prevention and Modification of Measles." Discussed by Drs Samuel Karelitz, New York, Clifford D Sweet, Oakland, Calif, Haven Emerson, New York, Franklin P Gengenbach, Denver, and Charles F McKhann, Boston.

Dr Philip M Stimson, New York, read a paper on "Individual Isolation." Discussed by Drs Haven Emerson, New York, Harry H Donnally, Washington, D C, Charles F McKhann, Boston, and Franklin P Gengenbach, Denver.

FRIDAY, JUNE 11—AFTERNOON

The following officers were elected: chairman, Dr Clifford D Sweet, Oakland, Calif; vice chairman, Dr Edward Shaw, San Francisco; secretary, Dr Albert D Kaiser, Rochester, N Y; executive committee: Dr Horton R Casparis, Nashville, Tenn, Dr Ralph M Tyson, Philadelphia, and Dr Clifford D Sweet, Oakland, Calif; delegate, Dr William Weston Columbia, S C; alternate, Dr John Aikman, Rochester, N Y; representative for Scientific Exhibit, Dr F T Mitchell, Memphis, Tenn.

Dr Albert D Kaiser, Rochester, N Y, presented the report of the executive committee as follows:

The executive committee recommends that the present Abraham Jacobi Memorial Fund Committee be continued; that Dr Ralph M Tyson, Philadelphia, be made a member of this committee to take the place of Dr Frederic W Schlutz, Chicago, whose term of office expires; that Dr Hugh L Dwyer, Kansas City, Mo, be added to the committee and be made secretary-treasurer to replace Dr Frank Neff, Kansas City, Mo, who wishes to retire from this office.

The executive committee recommends to the section that an invitation be extended to the International Pediatric Congress that meets in Rome, Italy, in September to hold its next meeting (1940) in the United States.

The executive committee wishes to call to the attention of the section the excellent and untiring work Dr Frank Neff of Kansas City has contributed in administering the Abraham Jacobi Memorial Fund.

The executive committee recommends that the secretary of the section meet with the committee.

Respectfully submitted

A GRAEME MITCHELL, Chairman
HORTON R CASPARIS
RALPH M TYSON

On motion of Dr Edgar P Copeland, Washington, D C, regularly seconded, it was voted that the report be adopted.

Dr Albert D Kaiser, Rochester, N Y, presented the report of the Abraham Jacobi Memorial Fund Committee as follows:

The activities of the Abraham Jacobi Memorial Fund during the year 1936-1937 include the completion of the Abraham Jacobi-Carl Schurz Memorial Park at Bolton Landing, Lake George, N Y. Reprints of the Memorial Park dedication exercises were mailed to all subscribers of the fund and to all medical libraries here and many of those abroad. The Jacobi Committee will see that the Memorial Park is kept in a nice condition. Another activity was the underwriting of the expense for publishing a supplement to the January (1937) issue of the AMERICAN JOURNAL OF DISEASES OF CHILDREN, which would otherwise not have been published because of the

cost and the lack of space. A small donation was solicited from pediatricians following the Kansas City meeting which helped to defray the above mentioned expenses.

No guest speaker was invited for this year. It is the present intention to limit foreign invitations for this purpose to special occasions and to speakers of exceptional appeal.

It is hoped that our modest fund will be kept intact for many years and be of service to the section through the interest-bearing income derived therefrom and that the friends of the section will continue their generous donations whenever it becomes advisable to ask for them to further the activities advised by the committee.

Respectfully submitted

FREDERIC W SCHULTZ, Chicago, 1937,
Chairman
ALFRED A WALKER, Birmingham, 1938
A GRAEME MITCHELL, Cincinnati, 1939
HORTON R CASPARIS, Nashville, 1940
FRANK C NEFF Kansas City Mo.,
Secretary-Treasurer

On motion of Dr Edgar P Copeland, Washington, D C, regularly seconded, it was voted that the report be adopted. Dr Edgar P Copeland, Washington, D C, presented the report of the resolutions committee as follows:

Your committee on resolutions begs to submit the following for your consideration:

1 The section desires to express its gratitude of the unbounded hospitality extended to the section by the local medical group, and in particular to Dr Crowe, our vice chairman together with Dr Nickman and Dr Stewart for their personal efforts in contributing to our comfort and happiness.

2 And, further, the section desires to express to the chairman, Dr Ralph Tyson, and to the secretary Dr Albert Kaiser, our appreciation for the arrangement of a most interesting and stimulating scientific program.

3 Since our last meeting we have lost through death a number of members and friends of the section. It is proposed that we rise for a moment in silent tribute to their memory.

Respectfully submitted

EDGAR P COPELAND
EDWARD B SHAW
WALTER B STEWART

On motion of Dr John Aikman, Rochester, N Y, regularly seconded, it was voted that the report be adopted.

Dr L Emmett Holt Jr, Baltimore, read a paper on "Abnormalities of Fat Metabolism in Childhood." Discussed by Drs S J Thannhauser, Boston, Harry Lowenburg Sr, Philadelphia and L Emmett Holt Jr, Baltimore.

Drs C A Stewart and E S Platon, Minneapolis, presented a paper on "Communicable Disease Control in Private Practice." Discussed by Drs Lee Forrest Hill, Des Moines, Iowa, Henry T Price Pittsburgh, Herman Schwarz New York, Clifford D Sweet, Oakland, Calif, Percival Nicholson, Ardmore, Pa and C A Stewart, Minneapolis.

Dr Milton B Cohen, Cleveland, read a paper on "The Allergic Crippled Child." Discussed by Drs J Alexander Clarke Jr, Philadelphia, W Ambrose McGee, Richmond Va, and Milton B Cohen, Cleveland.

Drs John L Rice, Samuel Frant and Harold Abramson, New York, presented a paper on "Epidemic Diarrhea of the New-Born. Preliminary Considerations on Outbreaks of Highly Fatal Diarrhea of Undetermined Etiology Among New-Born Babies in Hospital Nurseries." Discussed by Drs Hugh L Dwyer Kansas City, Mo, John Aikman Rochester, N Y, Walter D Ludlum, Brooklyn, Joseph Golomb, New York, and John L Rice, New York.

Dr E J Barnett, Spokane, Wash, read a paper on "Wood Tick Paralysis in Children."

Dr May G Wilson, New York, read a paper on "The Diagnosis of Heart Disease in Children. Consideration of Diagnostic Criteria Based on Analysis of Records of Five Hundred Children Observed in a Cardiac Clinic Over a Period of Three to Twenty Years." Discussed by Drs William D Stroud Philadelphia and Hyman Green, Boston.

SECTION ON PHARMACOLOGY AND THERAPEUTICS

WEDNESDAY, JUNE 9—AFTERNOON

The meeting was called to order at 2:05 by the chairman Dr N C Gilbert, Chicago.

Drs Robert L Levy, Alvan L Barach and Howard G Bruenn, New York, presented a paper on "Effects of Induced Oxygen Want in Patients with Cardiac Pain." Discussed by Drs H J Stewart, New York, T D Cunningham Denver, M Herbert Barker, Chicago, Alvan L Barach, New York, and Robert L Levy, New York.

Drs Harold Feil and Claude S Beck, Cleveland, presented a paper on "Treatment of Coronary Sclerosis and Angina Pectoris by Producing a New Blood Supply to the Heart." Discussed by Drs Wallace M Yater, Washington, D C, Herman Shube, Cleveland, Robert L Levy, New York, Claude S Beck, Cleveland, and Harold Feil, Cleveland.

Drs James A Greene, W D Paul and A E Feller, Iowa City, presented a paper on "The Action of Theophylline with Ethylenediamine on Intrathalacic and Venous Pressures in Cardiac Failure and on Bronchial Obstruction in Cardiac Failure and in Bronchial Asthma." Discussed by Drs G K Fenn, Chicago, T R Harrison, Nashville, Tenn, Alvan L Barach, New York, and James A Greene, Iowa City.

Drs Robert Goodhart and Norman Jolliffe, New York, presented a paper on "Observations on the Effects of Vitamin B (B₁₂) Therapy on the Polyneuritis of Alcohol Addicts." Discussed by Drs George R Cowgill, New Haven, Conn, Martin G Vorhaus, New York, Tom D Spies, Cincinnati, and Robert Goodhart, New York.

Drs Carl E Ervin and Henry F Hunt, Danville, Pa, presented a paper on "The Diagnosis and Treatment of Undulant Fever." Discussed by Drs Walter M Simpson, Dayton, Ohio, and Carl E Ervin, Danville, Pa.

Dr Waltman Walters, Rochester, Minn, presented a paper on "The Pathologic Physiology of the Common Bile Duct and Its Relation to Biliary Colic." Discussed by Drs A C Ivy, Chicago, Robert L Payne Norfolk, Va, R Russell Best, Omaha, and Waltman Walters, Rochester, Minn.

THURSDAY, JUNE 10—AFTERNOON

Dr N C Gilbert, Chicago, read the chairman's address, entitled "The Therapeutics of Coronary Circulation."

Dr Eugene M Landis, Philadelphia, read a paper on "Observations on Acacia Therapy in Nephrosis." Discussed by Dr A R Barnes, Rochester, Minn.

Dr Abraham Myerson, Boston, read a paper on "Human Autonomic Pharmacology." No discussion.

Drs D L Wilbur, A R MacLean and E V Allen, Rochester, Minn, presented a paper on "Clinical Observations on the Effects of Benzedrine Sulfate." No discussion.

Dr Laurence E Hines, Chicago, read a paper on "The Effect of Diuresis by Mercurials on the Clinical Course of Congestive Heart Failure." Discussed by Drs Arthur C DeGraff, New York, James G Carr, Chicago, Chauncey C Maher, Chicago, M Herbert Barker, Chicago, and Laurence E Hines, Chicago.

Drs Frank L Horsfall Jr, Kenneth Goodner, Colin M MacLeod and Albert H Harris 2d, New York, presented a paper on "Antipneumococcus Rabbit Serum as a Therapeutic Agent in Lobar Pneumonia." Discussed by Drs J G M Bullock, New York, Russell L Cecil, New York, Norman H Plummer, New York, and Frank L Horsfall, New York.

FRIDAY, JUNE 11—AFTERNOON

The following officers were elected: chairman, Dr Russell L Haden, Cleveland, vice chairman, Dr Erwin E Nelson, Ann Arbor, Mich, secretary, Dr Irving S Wright, New York, delegate, Dr Cary Eggleston, New York, alternate, Dr Chauncey D Leake, San Francisco, executive committee, Dr Russell L Haden, Cleveland, Dr N C Gilbert, Chicago, and Dr Chauncey D Leake, San Francisco.

The following papers were read as a symposium on "Prothamine Insulin":

Drs D A Scott, A M Fisher and C H Best, Toronto, Ont. "The Prolongation of Insulin Action."

Dr Herman O Mosenthal, New York "Protamine Zinc Insulin Clinical Application"

Dr Edwin J Kepler, Rochester, Minn "Protamine Insulin Clinical Experience"

Dr Elliott P Joslin, Boston "Difficulties in the Use of Protamine Insulin"

These four papers were discussed by Drs Walter R Campbell, Toronto, Ont., Carl H Greene, New York, Abraham Rudy, Boston, Herman O Mosenthal, New York, and Elliott P Joslin, Boston

SECTION ON PATHOLOGY AND PHYSIOLOGY

WEDNESDAY, JUNE 9—MORNING

The meeting was called to order by the chairman, Dr W E Garrey, Nashville, Tenn

Drs L G Rowntree, George M Dorrance and E F Ciccone, Philadelphia, presented a paper on "Sarcoma in Albino Rats Resulting from the Ingestion of a Crude Wheat Germ Oil Made by Ether Extraction" Discussed by Drs Oliver H Emerson, San Francisco, Richard Lewisohn, New York, and George M Dorrance, Philadelphia

Dr Laman A Gray, Baltimore, read a paper on "Krukenberg Tumors of the Ovary" Discussed by Drs Ellis Kellert, Schenectady, N Y, and Laman A Gray, Baltimore

The following applicants for Associate Fellowship were nominated Franklin Church Bing, Ph D, Evanston, Ill., Rev Francis J Dore, S J, M D, Boston, Mass, and Frank B Queen, M D, Denver

Dr Emil Novak, Baltimore, read a paper on "Disgerminoma of the Ovary" Discussed by Drs Karl M Wilson, Rochester, N Y, A S Giordano, South Bend, Ind, Norbert Enzer, Milwaukee, and Emil Novak, Baltimore

Dr Francis Carter Wood, New York, read a paper on "Changing Aspects in Tumor Pathology" No discussion

Dr Edwin E Osgood, Portland, Ore, read a paper on "Culture of Human Marrow The Length of Life of the Neutrophils, Eosinophils and Basophils of Normal Blood as Determined by Comparative Cultures of Blood and Sternal Marrow from Healthy Persons" Discussed by Drs Roy R Kracke, Atlanta, Ga, Max B Lurie, Philadelphia, W E Garrey, Nashville, Tenn, and Edwin E Osgood, Portland, Ore

Dr M C Winternitz, New Haven, Conn, read a paper on "Studies on the Pathology of Vascular Disease" No discussion

Drs William Dameshek and Henry Henstell, Boston, presented a paper on "The Diagnostic Value and the Limitations of the Trephine and Puncture Methods for Biopsy of the Sternal Bone Marrow" Discussed by Drs T S Kimball, Glendale, Calif, Edwin E Osgood, Portland, Ore, A S Giordano, South Bend, Ind, Roy R Kracke, Atlanta, Ga, E B Krumbhaar, Philadelphia, and William Dameshek, Boston

THURSDAY, JUNE 10—MORNING

Dr W E Garrey, Nashville, Tenn, read the chairman's address, entitled "Some Aspects of Cardiac Control"

The following papers were read as a symposium

Dr H C Bazett, Philadelphia "Calculation of Cardiac Output and Analysis of Cardiac Failure from Blood Pressure and Pulse Wave Velocity Measurements"

Dr Maurice B Visscher, Minneapolis "The Energy Metabolism of the Heart in Failure"

Dr C Sidney Burwell, Boston "The Placenta as a Modified Arteriovenous Fistula, Considered in Relation to the Circulatory Adjustments to Pregnancy"

Dr H B Williams, New York "Effect of Electric Shock on the Heart"

Drs J K Lewis and William Dock, San Francisco "The Origin of Heart Sounds and Their Changes in Myocardial Disease"

Drs Alfred Blalock, Nashville, Tenn and C Sidney Burwell, Boston "Constrictive Pericarditis Physiologic and Pathologic Considerations"

These six papers were discussed by Drs Isaac Starr Jr, Philadelphia, Charles C Wolferth, Philadelphia, George E

Fahr, Minneapolis, William Dock, San Francisco, H C Bazett, Philadelphia, Maurice B Visscher, Minneapolis, and C Sidney Burwell, Boston

The chairman appointed Drs Frank Hartman, Kenneth Lynch and Maurice B Visscher to serve as a nominating committee

FRIDAY, JUNE 11—MORNING

The following officers were elected chairman, Dr Roy R Kracke, Atlanta, Ga, vice chairman Dr Maurice B Visscher, Minneapolis, secretary, Dr J J Moore, Chicago, delegate Dr D J Davis, Chicago, alternate Dr J J Moore, Chicago, executive committee Dr Roy R Kracke, Atlanta, Ga, Dr W E Garrey, Nashville, Tenn, and Dr Henry C Sweany, Chicago, member of the American Board of Pathology, for six years, Dr E B Krumbhaar, Philadelphia

Drs Thomas Simpson and M Herbert Barker, Chicago, presented a paper on "A Study in Subcutaneous Oxygen Therapy" Discussed by Drs Henry C Sweany, Chicago, Clyde Brooks, New Orleans, Virgil Moon, Philadelphia, J H Bacon, Peoria, Ill, and M Herbert Barker, Chicago

Dr Frank W Hartman, Detroit, read a paper on "The Etiology and Pathogenesis of Brain Lesions Following Fever Therapy" Discussed by Drs Walter M Simpson, Dayton, Ohio, J M Nielsen, Los Angeles, Virgil Moon, Philadelphia, Clyde Brooks, New Orleans, and Frank W Hartman, Detroit

Dr Kenneth M Lynch, Charleston, S C, read a paper on "Pulmonary Asbestosis IV The Asbestosis Body and Similar Objects in the Lung" Discussed by Drs Henry C Sweany, Chicago and Kenneth M Lynch, Charleston, S C

Drs Paul H Harmon, William M Krigsten and Henry N Harkins, Chicago, presented a paper on "Problems Bearing on the Pathogenesis and Treatment of Acute Poliomyelitis" Discussed by Drs Henry N Harkins, Chicago, C W Jungeblut, New York, E C Rosenow, Rochester, Minn, and Paul H Harmon, Chicago

Drs S E Gould, Eloise, Mich, and I Forest Huddleson, East Lansing, Mich, presented a paper on "Diagnostic Methods in Brucella Infection" Discussed by Dr I Forest Huddleson, East Lansing, Mich

Drs Edward C Rosenow and Fordyce R Heilman, Rochester, Minn, presented a paper on "Streptococcal Infections Newer Methods of Study and Specific Treatment" Discussed by Drs Willard L Wood, Chicago, and Edward C Rosenow, Rochester, Minn

Drs Edwin G Bannick and Chester M Guernsey, Rochester, Minn, presented a paper on "The Erythrocyte Sedimentation Rate The Adequacy of a Simple Test and Its Practical Application in Clinical Medicine" No discussion

SECTION ON NERVOUS AND MENTAL DISEASES

WEDNESDAY, JUNE 9—AFTERNOON

The meeting was called to order at 2 o'clock by the chairman, Dr Henry R Viets, Boston

The following resolution was presented to the section by the secretary as coming from Dr Hans H F Reese, Madison, Wis

WHEREAS Several organizations interested in promoting human welfare have manifested a deep interest in research into the causation, prevention and treatment of mental disease and have furnished substantial financial aid to the prosecution of such research and

WHEREAS The Rockefeller Foundation, the John and Mary R Markle Foundation, the Josiah Macy Jr Foundation and the Supreme Council of the Scottish Rite of Freemasonry of the Northern Masonic Jurisdiction have been outstanding in giving moral and financial support to such research be it

Resolved That the House of Delegates of the American Medical Association on behalf of American psychiatry hereby records its gratitude for the valuable service rendered to the cause of psychiatric research by these organizations and that it heartily endorses the importance of studies looking to a solution of the problems of mental disease

On motion regularly made and seconded, the foregoing resolution was approved, to be transmitted to the House of Delegates

Drs Theodore C Ruch, John F Fulton and William J German, New Haven, Conn, presented a paper on "Sensory Discrimination in Monkey, Chimpanzee and Man After Lesions of the Parietal Lobe"

Dr J M Nielsen, Los Angeles, read a paper on "Gerstmann Syndrome of Finger Agnosia, Agraphia, Confusion of Right and Left, and Acalculia Comparison of This Syndrome with Disturbances of Body Scheme Resulting from Lesions of the Right Side of the Brain"

These two papers were discussed by Drs Joseph P Evans, Montreal, Israel S Wechsler, New York, Richard M Brickner, New York, Theodore C Ruch, New Haven, Conn, and J M Nielsen, Los Angeles

Dr Tracy J Putnam, Boston, read a paper on "Treatment of Athetosis by Section of Extrapyramidal Tracts in the Spinal Cord" Discussed by Drs Eric Oldberg, Chicago, John F Fulton, New Haven, Conn, Winthrop M Phelps, Baltimore, and Tracy J Putnam, Boston

The following papers were read as a symposium on "The Prefrontal Area"

Drs Carlyle F Jacobsen, G Finch and J L Kennedy, New Haven, Conn "Cortical Mechanisms in Emotion"

Dr Ward C Halstead, Chicago "Experimental Analysis of the Effects of Localized Cerebral Injury in Man"

Drs James W Watts and Walter Freeman, Washington, D C "Psychosurgery Effect on Certain Mental Symptoms of Surgical Interruption of Pathways in the Frontal Lobe"

These three papers were discussed by Drs H Douglas Singer, Chicago, Ralph W Barris, Washington, D C, Richard M Brickner, New York, S Spafford Ackerly, Louisville, Ky, Walter J Otis, New Orleans, Harold C Voris, Chicago, Theodore Diller, Pittsburgh, Paul C Bucy, Chicago, Walter Freeman, Washington, D C, Carlyle F Jacobsen, New Haven, Conn, and Ward C Halstead, Chicago

THURSDAY, JUNE 10—AFTERNOON

Vice Chairman Dr B Landis Elliott, Kansas City, Mo, presided

Dr Charles Armstrong, Washington, D C, read a paper on "Benign Lymphocytic Choriomeningitis Laboratory Studies with the Virus of and Their Bearing on the Infection in Man" Discussed by Drs Paul F Dickens, Washington, D C, Josephine B Neal, New York, Henry R Viets, Boston, and Charles Armstrong, Washington, D C

Dr Francis C Grant, Philadelphia, read a paper on "The Operative Treatment of Major Trigeminal Neuralgia" Discussed by Drs Walter E Dandy, Baltimore, M M Peet, Ann Arbor, Mich, Eric Oldberg, Chicago, and Francis C Grant, Philadelphia

Dr Eric Oldberg, Chicago, read a paper on "The Prognosis in Transverse Lesions of the Spinal Cord" Discussed by Drs James L Poppen, Boston, and Eric Oldberg, Chicago

Dr Albert P D'Errico, Dallas, Texas, read a paper on "A Surgical Procedure for Hydrocephalus with Spina Bifida" Discussed by Drs Tracy J Putnam, Boston, R Glen Spurling, Louisville, Ky, and Albert P D'Errico, Dallas, Texas

Dr Daniel V Conwell, Halstead, Kan, read a paper on "Vitamin Therapy of Muscular Dystrophy"

Drs Foster Kennedy and Alexander Wolf, New York, presented a paper on "A Clinical Evaluation of Quinine in Myotonia and of Prostigmin in Myasthenia"

These two papers were discussed by Drs Peter Bassoe, Chicago, B Landis Elliott, Kansas City, Mo, H E Himwich, Albany, N Y, Karl Rothschild, New Brunswick, N J, Daniel V Conwell, Halstead, Kan, and Alexander Wolf, New York

Dr Temple S Fay, Philadelphia, read a paper on "A Test for Diagnosis of Certain Headaches The Cephalalgigram" Discussed by Drs James W Watts, Washington, D C, Wilder Penfield, Montreal, James F McDonald, New York, and Temple S Fay, Philadelphia

FRIDAY, JUNE 11—AFTERNOON

Dr Henry R Viets presided

Dr Hans H F Reese, Madison, Wis, delegate of the section in the House, made a report on the session of the House of Delegates, which was accepted

Dr Walter Freeman, Washington, D C, made the following report as representative of the section on the American Board of Psychiatry and Neurology

The term of Dr Freeman, representing the section on the American Board of Psychiatry and Neurology, has expired and nominations are in order for his successor

At its meeting on June 2, the board unanimously voted to hold the June 1938 meetings and examinations in San Francisco, the date to conform with the meetings of the American Psychiatric Association

The next examinations to be given by the board will be held sometime during Christmas week in New York, tentatively the date now being considered is December 28

The tabulated information regarding certification of candidates during the fiscal year of 1937 may be of interest to the section

On motion, duly made and seconded, the report was accepted

The following officers were elected chairman, Dr Samuel D Ingham, Los Angeles, vice chairman, Groves B Smith, Godfrey, Ill, secretary, Paul C Bucy, Chicago, executive committee, H H F Reese, Madison, Wis, Henry R Viets, Boston, and Samuel D Ingham, Los Angeles, delegate, Tom B Throckmorton, Des Moines, alternate, Edward Delehanty,

TABLE 1—Certification of Candidates, December 1936

	Neurology	Psychiatry	Neurology and Psychiatry	Total
Class I (on record)	3	30	29	62
Class II (examination)	2	19	13	34
				96
Failed on examination		6	1	
Conditioned				
Anatomy and physiology	7			
Pathology and roentgenology	7			
Clinical neurology	1			
Psychobiology	1			
Psychopathology	4			

It must be realized that there is some duplication in figures under 'Conditioned' because many were conditioned in more than one subject. Also two of the conditions were given to candidates applying for both neurology and psychiatry in each case the candidate was passed and certified in psychiatry but conditioned in one subject for the certificate in neurology. Hence they are included under the subject of Class II—Psychiatry

TABLE 2—Certification of Candidates, June 1937

	Neurology	Psychiatry	Neurology and Psychiatry	Total
Class I (on record)	3	17	22	42
Class II (examination)	1	23	17	46
				88
Failed on examination		2	3	
Conditioned				
Anatomy and physiology	3			
Pathology and roentgenology	4			
Clinical neurology	3			
Clinical psychiatry	4			
Psychobiology	2			
Psychopathology	2			

Three of the conditions were given to candidates applying for both neurology and psychiatry in each case the candidate was passed and certified in psychiatry but conditioned in one subject for the certificate in neurology. Hence they also appear under Class II—Psychiatry

Denver, representative on American Board of Psychiatry and Neurology, Walter Freeman, Washington, D C, representative to Scientific Exhibit, Dr Roland P Mackay, Chicago

Dr Henry R Viets, Boston, read the chairman's address, entitled "Neurology, Past and Present"

Drs Frederick P Moersch and James W Kernohan, Rochester, Minn, presented a paper on "Hypoglycemia Neurologic and Neuropathologic Study" Discussed by Dr Frank N Allan, Boston

The following papers were read as a symposium on "Dementia Praecox"

Drs Joseph Wortis and Karl M Bowman, New York
"Hypoglycemia Insulin Treatment A Brief Review"

Drs D Ewen Cameron, Worcester, Mass and R G Hoskins, Boston 'Experiences in the Insulin-Hypoglycemia Treatment of Cases of Schizophrenia'

TABLE 3—Combined Table June and December

	Neurology	Psychiatry	Neurology and Psychiatry	Total
Class I	1	47	51	101
Class II	—	47	70	80
Previously certified	9	91	91	181
Total certified in all subjects to date				372
Divided as follows				
Psychiatry			172	
Neurology			19	
Psychiatry and neurology			181	
			—	372

Drs Charles A Rymer, John D Benjamin and Franklin G Ebaugh, Denver, on 'Hypoglycemia Treatment of Schizophrenia with Particular Reference to the Qualitative Study of Remissions A Preliminary Report'

These three papers were discussed by Drs Richard H Young, Omaha Lloyd H Ziegler, Albany, N Y Frank N Allan, Boston, Theodore R Robie, East Orange, N J Julius Steinfield, Peoria, Ill, Karl Dussik, Vienna, S T Gordy, Philadelphia, H E Himwich, Albany N Y, Walter Freeman, Washington, D C, J M Nielsen Los Angeles, R G Hoskins, Boston, Joseph Wortis, New York, D Ewen Cameron, Worcester, Mass, and Charles Rymer, Denver

Dr Frederick Lemere Medical Lake, Wash, read a paper on "Electro-Encephalography in the Psychoses" Discussed by Drs Hallowell Davis, Boston, Ralph W Gerard, Chicago and Frederick Lemere, Medical Lake, Wash

SECTION ON DERMATOLOGY AND SYPHILOLOGY

WEDNESDAY JUNE 9—AFTERNOON

The meeting was called to order at 2 10 by the chairman, Dr Paul A O'Leary, Rochester Minn

Dr David I Macht Baltimore read a paper on 'The Absorption of Drugs and Poisons Through Skin and Mucous Membranes' Discussed by Drs Isaac R Pels, Baltimore Theodore Cornbleet, Chicago, and David I Macht, Baltimore

Drs Elmore B Tauber and Leon Goldman, Cincinnati, presented a paper on "Hemiatrophia Facialis Progressiva" Discussed by Drs Earl D Osborne, Buffalo, Eugene Bernstein New York, Roy L Kile, St Louis, and Leon Goldman, Cincinnati

Drs John H Stokes and J Lamar Callaway, Philadelphia presented a paper on "Pyogenic Relapse and Light Sensitiveness in Certain Dermatoses Influence of an Intercurrent Infection Factor" Discussed by Drs Marion B Sulzberger, New York Samuel M Peck, New York, and John H Stokes, Philadelphia

Drs Roy L Kile and M F Engman Sr, St Louis, presented a paper on 'Further Investigations of the Relationship of Pityrosporum Ovale to Seborrheic Dermatitis' Discussed by Dr Richard S Weiss, St Louis, Morris Mohr, PhD St Louis, Drs H J Templeton Oakland, Calif Marion B Sulzberger New York, and Roy L Kile, St Louis

Dr Adolph G Kammer, East Chicago Ind, read a paper on "Torch Oil Dermatitis Its Relation to Epidermomycosis" Discussed by Drs Harry R Foerster, Milwaukee, Cleveland J White, Chicago, and Adolph G Kammer East Chicago, Ind

Dr Adolph B Loveman, Louisville, Ky, read a paper on "Stomatitis Venenata Report of an Unusual Case of Mucous

Membrane and Cutaneous Sensitivity to Oil of Anise" Discussed by Drs John Godwin Downing, Boston, David I Macht, Baltimore, Francis P McCarthy, Boston, Herbert Rattner, Chicago, and Adolph B Loveman, Louisville, Ky

Dr Elmer M Rusten, Minneapolis, read a paper on "The Results of Leukopenic Index Tests in Atopic Dermatitis" Discussed by Drs Warren T Vaughan, Richmond, Va, Harry M Robinson, Baltimore, Marion B Sulzberger, New York, and Elmer M Rusten, Minneapolis

THURSDAY, JUNE 10—AFTERNOON

The chairman, Dr Paul A O'Leary, Rochester Minn, announced that Dr Charles C Dennie Kansas City Mo, vice chairman of the section had been appointed to fill the vacancy on the executive committee left by the death of Dr Jeffrey C Michael

Dr Clark W Finnerud, Chicago, chairman of the Committee on Scientific Exhibit, presented the report of the committee as follows

This year we have had many of our usual handicaps We have had many unfortunate things happen We started out to have an exhibit centered around lesions of the mouth The response in general was rather poor, and those who were to be the center attractions of the exhibit were prevented from putting it on by illness, so that really had to be called off Therefore, we had a general exhibit this year

As you know, because of the publicity that has been given to syphilis, we turned over half the space to syphilis and the rest to truly dermatologic conditions And this year, unfortunately again, the papers did not lend themselves for the most part to space in the scientific exhibit We aim primarily, and want those who apply for places on the program next year to bear in mind the importance of working up their subject so that it can be demonstrated in the Scientific Exhibit That means a lot more to the members of the section and also to the general men who read the synopses of these papers

So far as the funds are concerned, as you know the American Medical Association helps us out, and has in recent years to some extent Of the money taken in four or five years ago when we passed the hat, we find that we have only spent about \$30 or \$40 in the past year leaving a healthy balance in the bank of \$117 33

It may be that we shall decide it would be most valuable for us to have an exhibit next year on disease of the mouth, and also we hope especially to illustrate as many of the papers as possible

We have had many favorable comments on this year's exhibit The exhibitors have been tireless in doing their part toward demonstrating their subject They have stayed right by the gun throughout the time, with very few exceptions, and that is important in putting over exhibits of this kind

This year we didn't capture quite as many prizes as usual, although it is rather an interesting exhibit The only prize taken by our section was by Dr Rhoda W Benham and Dr Edward D DeLamater, of New York, on Fungi

The chairman appointed the following members of the auditing committee Dr Fred Wise New York, Dr John Godwin Downing, Boston, and Dr Theodore Cornbleet, Chicago

The financial statement of the Committee on Exhibits was submitted to the auditing committee

Dr C Guy Lane, Boston, read the report of the American Board of Dermatology and Syphilology

Dr Howard Fox, New York, presented the following report with regard to the ARCHIVES OF DERMATOLOGY AND SYPHILOLOGY

Dr Pusey has said that the transactions are the most annoying part of handling the ARCHIVES I have recently sent mimeographed sheets to the various members of the societies which contribute transactions to the ARCHIVES Some of the members have followed those very nicely and I think some of them have thrown them in the wastebasket I would urge those who do send in case reports in their transactions to keep a carbon copy of the notes they send in and then read the ARCHIVES a few months later and compare, just look over changes that have been made Sometimes they will get a

little jolt I have gotten the same But it will help the transactions greatly if you will note the mistakes that were made

Just one other word with regard to the brevity of articles It has been said that our articles appear at a very late date in the ARCHIVES That is true Recently they have given us fifty more pages The last issue was quite a good deal thicker and that will continue until we get caught up

I am going to make it my business to try to induce or put pressure on all writers who send in unnecessarily long papers to try to make them shorter The longer the paper, it is said, the fewer the readers I think everybody would be glad to see articles shortened I am going to do the best I can to get authors to shorten their articles

The chairman called for the report of the Committee on Cosmetics There was no report

The chairman announced that the report of the Committee on Industrial Dermatoses would be given on Friday

Dr Fred Wise, New York, reported the acceptance and approval by the auditing committee of the financial statement submitted by the Committee on Exhibits It was moved, seconded and carried that the report be approved

On motion by Dr Howard Fox, New York, duly seconded, it was voted that the name of Prof Erich Hoffmann of Bonn, Germany, be submitted to the House of Delegates for Honorary Fellowship in the American Medical Association

Dr H N Cole, Cleveland, presented the following report with regard to the International Congress on Dermatology and Syphilology

At the meeting in Budapest two years ago last fall there was an invitation extended by the Spanish delegation that the next meeting be held in Madrid in 1939 or 1940 As time went on, this naturally became rather a conjecture, and there has been quite a little correspondence with the members of the permanent committee as to the status of the next congress Last April I received a cablegram, followed by a letter, from Drs Svend Lomholt, the secretary of the permanent committee, asking that an invitation be extended from the American colleagues At the time of the international congress there was also an invitation extended from the American group that we would be glad to have them come to New York, and when Madrid was selected, somewhat of an option was established that the next congress would come to America Now that the Madrid meeting is out of the question, there is a good possibility that we may have this congress in this country, if we care to extend an invitation There is to be a meeting of the permanent committee in Paris July 4 to discuss the place of the next meeting and the various problems connected with it Hence this report I might say that this year, and also last year, all checks that have been received from the various dermatologic societies in the United States have been turned over to the secretary and treasurer, Dr Svend Lomholt

On motion by Dr Paul Bechet, New York, duly seconded it was voted that the chair appoint a committee to cooperate with the American Dermatological Association to take action with regard to inviting our European confreres to an International Dermatological Congress to be held in New York, probably at a date to be set in the neighborhood of 1939

On motion by Dr Reuben Friedman, Philadelphia, duly seconded, it was voted that the following resolution be adopted

WHEREAS June 20 1937 marks the 250th anniversary of the discovery by Giovan Cosimo Bonomo and Diacinto Cestoni of the pathogenesis of scabies and

WHEREAS This discovery of the true nature of scabies definitely marks the beginning of the end of the doctrine of humoralism which doctrine as a pathologic concept has dominated medicine since the time of Hippocrates and of Galen and

WHEREAS The demonstration of the acarian origin of scabies constituted the first definite example in the history of medicine of the theory of specificity in the etiology of disease and

WHEREAS The modern anatomicopathologic period of dermatology inaugurated by Hebra really had its inception in the belated confirmation (Renucci 1834 Hebra 1844) of the great discovery by Bonomo and Cestoni therefore be it

Resolved That the Section on Dermatology and Syphilology of the American Medical Association authorize its secretary to send a message of greetings and felicitations to the Italian Society of Dermatology and

Syphilology and the Italian Society of the History of Medicine and the Natural Sciences on the occasion of their joint commemoration on June 20 1937—Scabies Day—of the very significant contribution to medicine that was made on June 20 250 years ago by their countrymen Giovan Cosimo Bonomo and Diacinto Cestoni

Dr Paul A O'Leary, Rochester, Minn, read the chairman's address, entitled "Present Day Status of Treatment of Neurosyphilis"

Drs Charles R Rein, Fred Wise and Alfred R Cukerbaum, New York presented a paper on "The Control and Prevention of Transfusion Syphilis Results of a Statistical Survey and Suggestions for a More Adequate Procedure for the Detection of Syphilis in All Donors" Discussed by Drs Harry L Baer, Pittsburgh, I W Kahn, New York George W Raiziss, Philadelphia, Herman Goodman, New York, John H Stokes, Philadelphia, and Charles R Rein, New York

Drs Joseph Earle Moore and Paul Padget, Baltimore, presented a paper on "The Problem of Seroresistant Syphilis (So-Called Wassermann Fastness)" Discussed by Drs J G Hopkins, New York, Paul A O'Leary, Rochester, Minn, and Paul Padget, Baltimore

Drs Charles W Barnett and George V Kulchar, San Francisco, presented a paper on "The Clinical Evaluation of Iodo-bismutol in the Treatment of Syphilis" Discussed by Drs M T Van Studdiford, New Orleans, John H Stokes, Philadelphia, Harold N Cole, Cleveland, Paul Bechet, New York, and George V Kulchar San Francisco

Drs Robert B Greenblatt and Everett S Sanderson, Augusta, Ga, presented a paper on "The Intradermal Chancroid Bacterial Antigen Skin Test as a Further Aid in the Differential Diagnosis of Venereal Diseases" Discussed by Drs Harold N Cole, Cleveland, George W Binkley, Cleveland, Marion B Sulzberger, New York and Robert B Greenblatt, Augusta, Ga

Drs John B Ludv and Edward F Corson, Philadelphia, presented a paper on "Lupus Erythematosus Its Increased Incidence in Philadelphia, with Studies Pertaining to the Disease" Discussed by Drs Maurice Myer Tolman, Boston, S William Becker, Chicago, Theodore Cornbleet Chicago M E Obermayer, Chicago, Paul Bechet, New York Richard S Weiss St Louis John B Ludv, Philadelphia and Edward F Corson, Philadelphia

Drs M E Obermayer and S William Becker Chicago, presented a paper on "Aminonium Succinimido Aurate A Gold Compound of Low Toxicity" Discussed by Drs Carroll S Wright, Philadelphia, and S William Becker, Chicago

FRIDAY, JUNE 11—AFTERNOON

The following officers were elected chairman, Joseph V Klauder, Philadelphia, vice chairman, H J Templeton, Oakland, Calif, secretary, Bedford Shelmire, Dallas, Texas, member of American Board of Dermatology and Syphilology, Howard Morrow, San Francisco, delegate, Clyde Cummer, Cleveland, alternate, Harold N Cole, Cleveland, representative to Scientific Exhibit Committee, Clark W Finerud, Chicago, executive committee, Harry R Foerster, Milwaukee, Paul A O'Leary, Rochester, Minn, and Joseph V Klauder, Philadelphia

Dr C Guy Lane, Boston, read the report of the Committee on Industrial Dermatoses On motion of Dr H J Templeton, Oakland, Calif, duly seconded and carried, the report was accepted and the chairman empowered to appoint the permanent committee designated therein The chairman appointed Drs C Guy Lane, Boston, chairman, Harry R Foerster, Milwaukee, John Godwin Downing, Boston Charles C Dennie, Kansas City, Mo, and Marion B Sulzberger, New York

The chairman reappointed the following Committee on the International Congress Drs Oliver S Ormsby, Chicago Elmore B Tauber, Cincinnati, C Guy Lane, Boston, Harold N Cole, Cleveland, and George M MacKee, New York

Dr Earl D Osborne, Buffalo, moved that the chairman appoint a committee to study the matter of establishing an American Academy of Dermatology, with geographic sections and with provisions for junior or associate memberships The motion was seconded and discussed with approval by Drs John

Godwin Downing, Boston, Elmore B Tauber, Cincinnati, and Everett S Lamm, Oklahoma City, who suggested that in the event of the consummation of these proposals the adoption of the ARCHIVES OF DERMATOLOGY AND SYPHILOLOGY as the journal of the academy be considered. The motion was carried. The chairman appointed the following committee to study the formation of an Academy of Dermatology: Drs Howard Fox, New York, Fred Wise, New York, Oliver S Ormsby, Chicago, Harry R Foerster, Milwaukee, M T Van Studdiford, New Orleans, H J Templeton, Oakland, Calif, and Richard S Weiss, St Louis.

Dr George W Binkley, Cleveland, read a paper on "Naevus Epithelioma Cylindromatosus." Discussed by Drs Fred D Weidman, Philadelphia, Richard L Sutton Jr, Kansas City, Mo, and George W Binkley, Cleveland.

Dr Richard J Bailey, Rochester, Minn, read a paper on "Relapsing Febrile Nodular Nonsuppurative Pemphigus." Discussed by Drs E W Netherton, Cleveland, and Richard J Bailey, Rochester, Minn.

Dr Herman Sharlit, New York, read a paper on "Melanin Production as Induced by an Aniline Derivative Dye (Indelible Pencil)." Discussed by Drs S William Becker, Chicago, Paul A O'Leary, Rochester, Minn, and Herman Sharlit, New York.

Drs Lester Hollander and Joseph M Shelton, Pittsburgh, presented a paper on "The Intra-Oral Use of Superficial X-Rays: A Report of the Use of the Chaoul Tube." Discussed by Drs Frederick M Jacob, Pittsburgh, A C Cipolaro, New York, H J Templeton, Oakland, Calif, S M Kaufman, New York, Harry R Foerster, Milwaukee, and Lester Hollander, Pittsburgh.

Dr Richard L Sutton Jr, Kansas City, Mo, read a paper on "Early Epidermal Neoplasia: Description and Interpretation. The Mutation Theory of the Origin of Cancer from a Dermatologic Standpoint." Discussed by Drs Everett C Fox, Dallas, Texas, Fred D Weidman, Philadelphia, and Richard L Sutton Jr, Kansas City, Mo.

Dr Jack G Hutton, Denver, read a paper on "Description of an Original Treatment for Warts." Discussed by Drs William Howard Hailey, Atlanta, Ga, and Harold N Cole, Cleveland.

The new officers were installed.

SECTION ON PREVENTIVE AND INDUSTRIAL MEDICINE AND PUBLIC HEALTH

WEDNESDAY, JUNE 9—MORNING

The meeting was called to order at 9 20 by the chairman, Dr L D Bristol, New York.

Dr W J McConnell, New York, read a paper on "Volatile Solvents as a Problem in Industrial Medicine." Discussed by Drs Henry Field Smyth, Philadelphia, Leon Lewis, Newark, N J, William Thau, Boston, Harold B Wood, Harrisburg, Pa, Millard Knowlton, Hartford, Conn, Zolton T Wirtschaffer, Cleveland, R R Sayers, Washington, D C, C P McCord, Detroit, and W J McConnell, New York.

Dr Yale Kneeland Jr, New York, read a paper on "Filterable Viruses in Infection of Human Upper Respiratory Tract." Discussed by Drs Russell L Cecil, New York, L D Bristol, New York, Henry F Vaughan, Detroit, M L Blatt, Chicago, and Yale Kneeland Jr, New York.

Dr L D Bristol, New York, read the chairman's address, entitled "Next Steps in the Organization and Administration of Preventive and Industrial Medicine and Public Health." Discussed by Drs Holman Taylor, Fort Worth, Texas, and Stanley Nichols, Asbury Park, N J.

Dr R E Dyer, Washington, D C, read a paper on "Animal Reservoirs and Endemic Typhus." Discussed by Drs John J Phair, Baltimore, J N Baker, Montgomery, Ala, J C Geiger, San Francisco, G H Coombs, Augusta, Maine, James A Hayne, Columbia, S C, John A Ferrell, New York, and R E Dyer, Washington, D C.

THURSDAY, JUNE 10—MORNING

Dr Philip B Matz, Washington, D C, read a paper on "A Study of Silicosis." Discussed by Drs R R Sayers, Washington, D C, M James Fine, Newark, N J, M P Messenger, Oakfield, N Y, and Philip B Matz, Washington, D C.

Dr S A Weisman, Minneapolis, read a paper on "Correlation on the Positive Tuberculosis Reaction and the Shape of the Chest." Discussed by Drs Harry Bakwin, New York, Haven Emerson, New York, L M Rohr, Brooklyn, and S A Weisman, Minneapolis.

Dr W Ambrose McGee, Richmond, Va, read a paper on "The Relative Value of Schilling Differential Counts, the Sedimentation Rates and Lymphocyte-Monocyte Ratios in Tuberculosis of Childhood." Discussed by Drs Frank B Stafford, Charlottesville, Va, J I Linde, New Haven, Conn, and W Ambrose McGee, Richmond, Va.

Dr Henry F Vaughan, Detroit, read a paper on "Intensive Case Finding Work on Tuberculosis." Discussed by Drs Esmond R Long, Philadelphia, Haven Emerson, New York, E R Hayhurst, Columbus, Ohio, J I Linde, New Haven, Conn, A E Jaffin, Jersey City, N J, L M Rohr, Brooklyn, and Henry F Vaughan, Detroit.

Drs Paul A Neal and R R Jones, Washington, D C, presented a paper on "Chronic Mercurialism in the Hatters' Fur-Cutting Industry." Discussed by Drs D Chester Brown, Danbury, Conn, C P McCord, Detroit, Haven Emerson, New York, R R Sayers, Washington, D C, E R Hayhurst, Columbus, Ohio, Millard Knowlton, Hartford, Conn, D Chester Brown, Danbury, Conn, and Paul A Neal, Washington, D C.

FRIDAY, JUNE 11—MORNING

The following officers were elected: chairman, Dr Robert Legge, Berkeley, Calif, vice chairman, Dr Charles Craster, Newark, N J, secretary, Dr Irl C Riggan, Richmond, Va, executive committee: Dr R R Sayers, Washington, D C, Dr L D Bristol, New York, and Dr Robert Legge, Berkeley, Calif, delegate, Dr Stanley H Osborn, Hartford, Conn, alternate, Dr R R Sayers, Washington, D C.

Dr C D Selby, Detroit, in the absence of Dr A L Brooks, Detroit, read the following report of the Committee on Accident Control:

This committee recognizes that accidents, affecting as they do, the health and well being of the public, are a matter of great concern to the medical profession at large, and more particularly to those physicians whose chief interest is preventive and industrial medicine, and public health. The committee has therefore contacted some of the leading industrial physicians and city and state health department officials with the purpose of ascertaining what steps should be taken to best promote safety.

Many valuable suggestions were offered. It is the feeling in general that all activity among physicians should be directed toward cooperation with the existing, well organized bodies whose chief business it is to control accidents, namely, the National Safety Council, the various local safety organizations, the City Traffic Control Bureaus, and so on. This cooperation may consist of physical or mental examination of drivers, or others whose activity might affect safety of others, improvement in technique or equipment, in making these examinations, the keeping of adequate records of injuries to the end that more may be known of the manner in which they were caused, hence the prevention, cooperation with school authorities in teaching the principles of safety to children.

Such questions as the effect of alcohol on drivers, of fatigue, of emotional upsets, of poor vision, can best be studied by physicians. The importance of this work is now generally accepted and herein lies the greatest opportunity for the physician.

A L BROOKS, M D, Detroit

On motion made by Dr C D Selby, Detroit, seconded by Dr Stanley H Osborn, Hartford, Conn, it was voted that the Report of the Committee on Accident Control be accepted and presented to the authorities of the American Medical Association for whatever further disposition may be desirable.

Dr Stanley H Osborn, delegate to the House, gave a report on the action of the House of Delegates at this session

Dr Herman Gold, Chester, Pa, read a paper on "Active Immunization of Human Beings with Tetanus Toxoid, Alum Precipitated, Refined" Discussed by Drs Louis Tuft, Philadelphia, L D Bristol, New York, and Herman Gold, Chester, Pa

Drs Thomas Parran, Washington, D C, H H Hazen, Washington, D C, J F Mahoney, Stapleton, Staten Island, N Y, Arthur H Sanford, Rochester, Minn, F E Senear, Chicago, and Walter M Simpson, Dayton, Ohio, presented a paper on "Serodiagnostic Tests for Syphilis as Performed by Thirty-Nine State Laboratories Comparative Study" Discussed by Drs Frederick H Lamb, Davenport, Iowa, Stanley H Osborn, Hartford, Conn, and Walter M Simpson, Dayton, Ohio

Dr Walter Clarke, New York, read a paper on "The Campaign Against Syphilis in New York City" Discussed by Drs Charles C Dennie, Kansas City, Mo, Carl A Wilzbach, Cincinnati, Howard Morrow, San Francisco, Stanley H Osborn, Hartford, Conn, and Walter Clarke, New York

Dr C D Selby, Detroit, read a paper on "Industrial Preventive Medicine A Plan for Control of Occupational Diseases" Discussed by Drs G H Gehrman, Wilmington, Del, Alvin W Schoenleber, New York, Harold B Wood, Harrisburg, Pa, and C D Selby, Detroit

Drs R B Cram and Morris E Missal, Rochester, N Y, presented a paper on "The Management of the Cardiac Patient in Industry" Discussed by Drs Ernest B Boas, New York, W D Stroud, Philadelphia, and R B Cram, Rochester, N Y

Dr D A Bennett, Canton, Ill, read a paper on "Personal Experiences with Gas Bacillus Infection" Discussed by Drs Kellogg Speed, Chicago, James F Kelly, Omaha, and D A Bennett, Canton, Ill

SECTION ON UROLOGY

WEDNESDAY, JUNE 9—MORNING

The meeting was called to order at 9 10 by the chairman, Dr Henry W E Walther, New Orleans

The following papers were read as a symposium on "Pediatric Urology"

Drs Lawrence R Wharton and Harriet G Guild, Baltimore "The Late Effects of Acute Pyelitis in Female Children"

Dr Meredith F Campbell, New York "Primary Malignant Tumors of the Urogenital Tract in Infants and Children"

Dr Alexander B Hepler, Seattle "Nonobstructive Upper Urinary Tract Dilatations in Children"

These three papers were discussed by Drs Vincent Vermooten, Johannesburg, South Africa, Henry F Helmholz, Rochester, Minn, Albert E Goldstein, Baltimore, William E Stevens, San Francisco, William F Braasch, Rochester, Minn, and Alexander B Hepler, Seattle

Drs O S Lowsley and Cohn Luke Begg, New York, presented a paper on "A Three-Stage Operation for Repair of Hypospadias" Discussed by Dr J Eastman Sheehan, New York

Dr Hugh H Young, Baltimore, introduced Prof Reynaldo Dos Santos, Lisbon, Portugal

Drs Alexander Randall, Philadelphia, read a paper on "Studies on the Pathology of the Renal Papilla and the Relationship to Renal Calculus"

Drs James T Priestley and William F Braasch, Rochester, Minn, presented a paper on "Silent Renal Calculi"

Drs William J Ezickson and Jacob B Feldman, Philadelphia, presented a paper on "Signs of Vitamin A Deficiency in the Eye Correlated with Urinary Lithiasis"

These three papers were discussed by Drs Leon Herman, Philadelphia, Linwood D Keyser, Roanoke, Va, John H Morrissey, New York, Miley B Wesson, San Francisco, Stanley R Woodruff, Jersey City, N J, Henry Sangree, Philadelphia, Alexander Randall, Philadelphia, and William J Ezickson, Philadelphia

Dr Hugh H Young, Baltimore, read a paper entitled "Remarks on Surgery of the Prostate" Discussed by Dr N G Alcock, Iowa City

THURSDAY, JUNE 10—MORNING

Dr Reynaldo Dos Santos, Lisbon, Portugal, a visitor to the section, presented a talk with lantern demonstration on Arterionography in Relation to Renal Diagnosis

Dr John M Pace, Dallas, Texas, read a paper on "The Effect of Neoarsphenamine in Urinary Infections"

Dr Henry W E Walther, New Orleans, read the chairman's address, entitled "Urinary Antisepsis"

These two papers were discussed by Drs Anson L Clark, Oklahoma City, Monroe E Greenberger, New York, and Henry F Helmholz, Rochester, Minn

Drs Herman L Kretschmer and A E Kanter, Chicago, presented a paper on "Effect of Certain Gynecologic Lesions on the Upper Urinary Tract" Discussed by Drs Rosemary Shoemaker, Rochester, Minn, William E Stevens, San Francisco, and Herman L Kretschmer, Chicago

The following papers were read as a symposium on "Genito Urinary Malignancy"

Dr Henry A R Kreutzmann, San Francisco "The Treatment of Primary Carcinoma of the Male Urethra"

Drs Frank Hinman, San Francisco, and T O Powell, Los Angeles, "Recent Advances in the Diagnosis and Treatment of Tumor of the Testis"

Dr O A Nelson, Seattle "Malignant Growths of the Bladder"

Dr Theodore R Fetter, Philadelphia "Renal Neoplasms A Review of Cases and Indications for Treatment"

Dr Arbor D Munger, Lincoln, Neb, "The Treatment of Urinary Tract Malignancy with Supervoltage Roentgen Irradiation"

These five papers were discussed by Drs H C Bumpus Jr, Pasadena, Calif, James L Estes, Tampa, Fla, Russell S Ferguson, New York, Alfred F Hocker, New York, Lloyd G Lewis, Baltimore, Victor D Lespinasse, Chicago, Leon Herman, Philadelphia, and Frank Hinman, San Francisco

FRIDAY, JUNE 11—MORNING

The following officers were elected chairman, Dr Albert J Scholl, Los Angeles, vice chairman, Dr George Reinle, Oakland, Calif, secretary, Dr William P Herbst, Washington, D C, delegate, Dr H C Bumpus Jr, Pasadena, Calif, alternate, Dr George Reinle, Oakland, Calif, executive committee, John H Morrissey, New York, Henry W E Walther, New Orleans, and Albert J Scholl, Los Angeles

Dr George R Livermore, Memphis, Tenn, read a paper on "Decapsulation and Nephrostomy in Anuria" Discussed by Drs Nelse F Ockerblad, Kansas City, Mo, A I Dodson, Richmond, Va, and George R Livermore, Memphis, Tenn

Dr Roger W Barnes, Los Angeles, read a paper on "Teaching Urology to Medical Students" Discussed by Drs George F Cahill, New York, Nelse F Ockerblad, Kansas City, Mo, R M Le Comte, Washington, D C, Dr N G Alcock, Iowa City, and Roger W Barnes, Los Angeles

The following papers were read in a Symposium on "Gonococcal Infections"

Dr R A Vonderlehr, Washington, D C "The Gonorrhea Problem in the United States"

Dr J A C Colston, John E Dees and Henry C Harnill, Baltimore "The Treatment of Gonococcal Infections with Sulfanilamide"

Dr Charles M Carpenter, Rochester, N Y "An Evaluation of Laboratory Methods for the Diagnosis of Gonococcal Infection in the Male"

Drs S L Warren, and W W Scott, Rochester, N Y "Artificially Induced Fever for the Treatment of Gonococcal Infections in the Male"

These four papers were discussed by Drs William Bierman, New York, Henry B Gwynn, Washington, D C, Ralph H Jenkins, New Haven, Conn, Emily Dunning Barringer, New

York, Frederick A Reuter, Washington, D C, Andrew Peterson, New York, Percy Pelouze, Philadelphia, Perrin H Long, Baltimore, Walter G Maddock, Ann Arbor, Mich, William P Herbst, Washington, D C, J A C Colston, Baltimore, Charles M Carpenter, Rochester, N Y, and S L Warren, Rochester, N Y

SECTION ON ORTHOPEDIC SURGERY

WEDNESDAY, JUNE 9—MORNING

The meeting was called to order at 9 05 by the chairman, Dr Fremont A Chandler, Chicago

The following were appointed as the nominating committee of the section Dr William Barnett Owen, Louisville, Ky, chairman, Dr Benjamin P Farrell, New York, and Dr Melvin S Henderson, Rochester, Minn

Drs E L Elason and John Paul North, Philadelphia, presented a paper on "Methods of Treatment and Results in Fractures of the Shaft of the Femur" Discussed by Drs Frederick C Kidner, Detroit, P H Scardino, Houston, Texas, and Willis C Campbell, Memphis, Tenn

Dr W H Von Lackum, New York read a paper on "End Result of Twenty-One Years of Spine Fusion for Tuberculosis" Discussed by Drs Walter Scott, Sioux City, Iowa and Roland Hammond, Providence, R I

Dr J Dewey Bisgard, Omaha, read a paper on "The Etiology of Cartilaginous Exostoses and Giant Cell Tumors of the Bone" Discussed by Drs L D Smith, Milwaukee Marion Beckett Howorth, New York, I William Nachlas, Baltimore, and J Dewey Bisgard, Omaha

Dr Eben J Carey, Milwaukee, read a paper on "Wave Mechanics of Muscular and Nervous Actions, the Dynamic Relativity of the Pressure in Nerve, Muscle and Bone" Discussed by Drs Melvin S Henderson, Rochester, Minn, Arthur Steindler, Iowa City, and Eben J Carey, Milwaukee

Dr W T Hammond, Easton, Md, read a paper on "The Importance of Adequate Fracture Treatment in Rural Hospitals" Discussed by Dr George E Bennett, Baltimore, Voigt Mooney, Pittsburgh, and W T Hammond, Easton Md

Dr Leo Mayer, New York, read a paper on "A Comparative Study of the Surgical and Nonoperative Method of Treating Bone and Joint Tuberculosis" Discussed by Drs Benjamin P Farrell, New York, F C Kidner, Detroit, George E Bennett, Baltimore, Arthur Steindler, Iowa City, A Bruce Gill, Philadelphia, and Leo Mayer, New York

THURSDAY, JUNE 10—MORNING

Drs W J Mixer, J S Barr and A O Hampton, Boston, presented a paper on "Intervertebral Disk Lesions" Discussed by Drs George I Bauman, Cleveland, Samuel J Lang, Evanston, Ill, F L Reichert, San Francisco, Philip Lewin, Chicago, and W J Mixer, Boston

Drs R Glen Spurling and F H Mayfield, Louisville, Ky, presented a paper on "Hypertrophy of the Ligamenta Flava as a Cause of Low Back Pain" Discussed by Drs G E Haggart, Boston, Charles Murray Gratz, New York, Frank R Ober, Boston, and R Glen Spurling, Louisville, Ky

Dr Frank R Ober, Boston, read a paper on "Fasciotomy for the Relief of Sciatica and Some Mechanical Disturbances of the Low Back" Discussed by Drs Alan DeF Smith, New York, Frank D Dickson, Kansas City, Mo, Edwin W Ryerson, Chicago, Marion Beckett Howorth, New York, G E Haggart, Boston, and Frank R Ober, Boston

Drs Arthur Steindler and James Vernon Luck, Iowa City, presented a paper on "Differential Diagnosis in Low Back Pain" Discussed by Drs William Barnett Owen, Louisville, Ky, A R Shands Jr, Durham, N C, and Arthur Steindler, Iowa City

Dr R Watson Jones, Liverpool, England, read a paper on "Arthrodesis in Osteo-Arthritis of the Hip"

Dr John G Kuhns, Boston, read a paper on "Care of the Feet in Chronic Arthritis" Discussed by Drs Louis E Papurt, Cleveland, and John P Stump, New York.

FRIDAY, JUNE 11—MORNING

The following officers were elected chairman, John Dunlop, Pasadena, Calif, vice chairman, Oscar L Miller, Charlotte, N C, secretary, Robert V Funsten, Charlottesville Va, executive committee, Arthur T Legg Boston, Fremont A Chandler, Chicago, John Dunlop, Pasadena, Calif, delegate, Roland Hammond, Providence, R I alternate, Hulett J Wyckoff, Seattle Drs Willis C Campbell, Memphis, Tenn and Frank R Ober, Boston, were nominated, the Board to select one as a member of the American Board of Orthopedic Surgery

The report of the secretary was given by Dr Robert V Funsten and was adopted

Dr Fremont A Chandler, Chicago, made the following report for the examining board "On Monday and Tuesday of this week we held our first examinations of 1937 We originally had 138 candidates for admission and actually examined 129 Another examination will be given by this board in January, just before the meeting of the academy at Los Angeles It is requested that all candidates have their applications before this board three months prior to the examination That is necessary because of the large numbers who have applied We now have over eighty applications awaiting action coming from men who could not be accommodated at this meeting We think the board is on a good, firm foundation now It is functioning and I can assure you that the members of the board are making a very earnest effort to have this board function in behalf of orthopedic surgeons, and they feel that a man whose work is only partially that of an orthopedic surgeon cannot expect to be going under the guise of an orthopedic surgeon This work must consist—a great majority of it—of orthopedic surgery A man who does a lot of obstetrics and some orthopedic surgery and may have several cases during the year can hardly expect to be considered an orthopedic specialist It does not, however, mean that the candidate's work must be exclusively limited to orthopedic surgery In certain communities, especially, it is impossible for him to avoid some other type of work, but if it is a minority of his practice that will be given due consideration A second examination in 1938 will be given in conjunction with the Americal Medical Association That happens to fall in San Francisco Whether or not arrangements can be made to hold an examination on the East Coast or in the Middle West between those times I cannot say at the present time The examinations up to date have consisted of examinations in the Middle West or East The men on the West Coast have had no chance"

Dr Ralph K Ghormley, Rochester, Minn, read a paper on "Pathologic Fractures" Discussed by Drs Joseph A Freiberg, Cincinnati, Philip Lewin, Chicago, and Ralph Ghormley, Rochester, Minn

Drs A C Ivy and Smith Freeman, Chicago, presented a paper on "The Occurrence of an Osseous Dyscrasia in Gastrectomized Puppies" Discussed by Drs Walter G Stuck, San Antonio, Texas, and A C Ivy, Chicago

Dr Willis C Campbell, Memphis, Tenn, read a paper on "Malumted Colles Fractures" Discussed by Drs Frank D Dickson, Kansas City Mo, George E Bennett, Baltimore, Donald C Durman, Saginaw, Mich, and Willis C Campbell, Memphis, Tenn

Dr Fremont A Chandler, Chicago, read the chairman's address, entitled "Localized Overgrowth of the Extremities and Spine"

Dr Roland Hammond, Providence, R I, delegate, gave a report of the session of the House of Delegates

Drs D B Phemister and Henry N Harkins, Chicago, presented a paper on "Simplified Technic of On Lay Grafts for All Ununited Fractures in Acceptable Position" Discussed by Drs Willis C Campbell, Memphis, Tenn, W K West, Oklahoma City, Melvin S Henderson Rochester, Minn, Elven J Berkhiser, Chicago, Edwin W Ryerson, Chicago and D B Phemister, Chicago

Dr H W Spiers, Los Angeles read a paper on 'Comminuted Fractures of the Os Calcis' Discussed by Drs J A Link, Springfield Ohio, and H W Spiers, Los Angeles

SECTION ON GASTRO-ENTEROLOGY
AND PROCTOLOGY

WEDNESDAY, JUNE 9—AFTERNOON

The meeting was called to order at 2 05 by the chairman, Dr Louis A Bue, Rochester, Minn

Drs Sidney A Portis and Richard Hermann Jaffe, Chicago, presented a paper on "A Study of Peptic Ulcer from Necropsy Records" Discussed by Drs Sara M Jordan, Boston, John L Kantor, New York, Clayton W Greene, Buffalo, George B Eusterman, Rochester, Minn, Richard Hermann Jaffe, Chicago, and Sidney A Portis, Chicago

Drs T Grier Miller, Philadelphia, W Osler Abbott, Wynnewood, Pa, and Walter G Karr, Philadelphia, presented a paper on "The Influence of the Duodenum on the Concentration of Dextrose After Its Administration in Hypertonic Solution" Discussed by Drs Eugene P Pendergrass, Philadelphia, Harry Shay, Philadelphia, T L Althausen, San Francisco, and T Grier Miller, Philadelphia

Dr Irvin Abell, Louisville, Ky, read a paper on "Acute Abdominal Catastrophes" Discussed by Drs Frank H Lahey, Boston, Robert Lee Payne, Norfolk, Va, Harvey B Stone, Baltimore, Samuel Moren, Providence, Hyman I Goldstein, Camden, N J, M G Wohl, Philadelphia, John Fallon, Worcester, Mass, and Irvin Abell, Louisville, Ky

Dr George Henry Thiele, Kansas City, Mo, read a paper on "Coccygodynia and Pain in the Superior Gluteal Region and Down the Back of the Leg Observations on the Causation of Such Pain by Tonic Spasm of the Levator Ani, Coccygeus and Piriformis Muscles, and Its Relief by Massage of These Muscles" Discussed by Drs Fernando I Wilson, Kansas City, Mo, Edward G Martin, Detroit, E H Terrell, Richmond, Va, and George Henry Thiele, Kansas City, Mo

Drs Malcolm Robert Hill and Cyril Brian Courville, Los Angeles, presented a paper on "Vesical Dysfunction Following Abdominoperineal Resection of Carcinoma of Rectum" Discussed by Drs Dudley A Smith, San Francisco, Descum C McKenney, Buffalo, Edward G Martin, Detroit, and Malcolm Robert Hill, Los Angeles

Dr Edward Holman Skinner, Kansas City, Mo, read a paper on "Mucosal Pattern Technique and Kymographic Records of the Esophagus and Stomach" Discussed by Drs Lester Levyn, Buffalo, Wendel G Scott, St Louis, and Edward Holman Skinner, Kansas City, Mo

Dr Jesse Louis Bollman, Rochester Minn, read a paper on "The Formation and Treatment of Experimental Peptic Ulcers Produced by Cinchophen" Discussed by Drs George B Eusterman, Rochester, Minn, Lester R Dragstedt, Chicago, A F R Andresen, Brooklyn, and Jesse Louis Bollman, Rochester, Minn

THURSDAY, JUNE 10—AFTERNOON

Dr Louis A Bue, Rochester, Minn, read the chairman's address, entitled "The Value of Specialization in Medicine"

Dr Dudley A Smith, San Francisco, presented a motion picture entitled "Management of Colostomy" Discussed by Drs Thomas E Jones, Cleveland, Rollin R Best, Omaha and Dudley A Smith, San Francisco

Dr Samuel Allen Wilkinson, Boston, read a paper on "Chronic Cholecystitis versus Irritable Colon" Discussed by Drs Carl H Greene, New York, Clarence F G Brown, Chicago, Russell S Boles, Philadelphia, Rudolf Schindler, Chicago, Sidney A Portis, Chicago, B B Vincent Lyon, Philadelphia, Manfred Kraemer, Newark, N J, Anthony Bassler, New York, Samuel Friedman, New York, and Samuel Allen Wilkinson, Boston

Drs Philip Walling Brown and D M Marcle, Rochester, Minn, presented a paper on "What Happens to Patients Who Have Diverticulosis and Diverticulitis of the Colon" Discussed by Drs Henry L Bockus, Philadelphia, Julius Friedenwald, Baltimore, and Philip Walling Brown, Rochester, Minn

Dr Daniel Nathan Silverman, New Orleans, read a paper on "A New Method of Diagnosis in Bacillary Dysentery" Discussed by Drs John H Musser, New Orleans, Joseph Felsen, New York, and Daniel Nathan Silverman, New Orleans

Dr John Milton McCaughan, St Louis, read a paper on "Pancreatic Fistula" Discussed by Drs Howard M Clute,

Boston, William T Coughlin, St Louis, John J Gilbride, Philadelphia, Rolf Lum, Boston, A C Ivy, Chicago, and John Milton McCaughan, St Louis

Drs Louis Edward Barron, New Haven, Conn, and George Morris Curtis, Columbus, Ohio, presented a paper on "Gastric Motor Disturbances Following Laparotomy" Discussed by Drs A F R Andresen, Brooklyn, Stockton Kimball, Buffalo, and Louis Edward Barron, New Haven, Conn

FRIDAY, JUNE 11—AFTERNOON

The following officers were elected chairman, Dr Henry L Bockus, Philadelphia, vice chairman, Dr Descum C McKenney, Buffalo, secretary, Dr A H Aaron, Buffalo, executive committee Dr Ernest H Gaiter, Baltimore, Dr Louis A Bue, Rochester, Minn, and Dr Harry L Bockus, Philadelphia, delegate, Dr Curtice Rosser, Dallas, Texas, alternate, Dr Louis A Bue, Rochester, Minn, chairman Committee on Section Exhibit, Dr J Arnold Bergen, Rochester, Minn

Dr Anthony Bassler, New York, introduced the following resolution

Resolved That the Section on Gastro Enterology and Proctology of the American Medical Association extend an invitation to the International Society of Gastro Enterology to hold their third congress in the United States in 1939 (Dr George BroLee 64 rue de Concord Brussels Belgium)

On motion, seconded by Dr Henry L Bockus, Philadelphia, the resolution was adopted

Dr George Ernest Binkley, New York, read a paper on "Treatment of Operable Rectal and Anal Cancer in Poor Surgical Risks" Discussed by Drs Douglas Quick, New York, Clement Joseph De Bere, Chicago, and George Ernest Binkley, New York

Drs Burrill Bernard Crohn and Albert Ashton Berg, New York, presented a paper on "Right-Sided Colitis Life History and Treatment" Discussed by Drs Richard B Cattell, Boston and Burrill Bernard Crohn, New York

Drs Ernest Howard Gaiter, Baltimore, and James L Borland, Jacksonville, Fla, presented a paper on "Gastritis Gastroscopic Studies" Discussed by Drs Edward Benson Benedict, Newton Center, Mass, Rudolf Schindler, Chicago, William A Swalm, Philadelphia, Burrill Bernard Crohn, New York, James L Borland, Jacksonville, Fla, and Ernest Howard Gaiter, Baltimore

Dr Anthony Bassler, New York, read a paper on "The Importance of Surgery in Hematemesis Accompanied with Pyloric Obstruction" Discussed by Drs Charles Gordon Heyd, New York, Thomas T Mackie, New York, Albert J Sullivan, New Haven, Conn, John M Blackford, Seattle, and Anthony Bassler, New York

Dr Paul Brown Welch, Miami, Fla, read a paper on "The Mechanism of Production of Digestive Symptoms Associated with Urologic Disturbances" Discussed by Drs Charles L Hartsock, Cleveland, Clarence G Bandler, New York, Lester M Morrison, Philadelphia, Anthony Bassler, New York, Samuel Friedman, New York, and Paul Brown Welch, Miami, Fla

Dr Lay Martin, Baltimore, read a paper on "Low Grade Partial Small Intestine Obstruction" Discussed by Drs Julius Friedenwald, Baltimore, and Lay Martin, Baltimore

Dr Moses Paulson, Baltimore, read a paper on "A Diagnostic Intradermal Reaction with Bowel Antigen Indicating Presence of Lymphogranuloma Inguinale Virus in Intestine and Differentiating Colitides Associated with Lymphogranuloma Inguinale Virus" Discussed by Drs Irving Gray, Brooklyn, and Moses Paulson, Baltimore

SECTION ON RADIOLOGY

WEDNESDAY, JUNE 9—AFTERNOON

The meeting was called to order at 2 10 by the chairman, Dr Ross Golden, New York

Drs Wallace M Yater and Eugene R Whitmore, Washington, D C, presented a paper on "Histopathologic Study of Tissues of Patients Injected with Thorium Dioxide Sol for Hepatosplenography" Discussed by Drs William H Stewart, New York, Robert B Taft, Charleston, S C, Clifford R Orr, Buffalo, and Lester Levyn, Buffalo

Dr Sidney E Johnson, Louisville, Ky, read a paper on "Some Clinical Applications of Roentgen Kymography." Discussed by Drs W B Fisor, Baltimore, Marcy L Sussman, New York, and Wendell G Scott, St Louis

Dr Ross Golden, New York, read the chairman's address, entitled "Comments on Prepyloric Gastritis and Spasm"

Dr Joseph Jellin, Los Angeles, read a paper on "Regional Ileitis Its Present Status" Discussed by Drs James T Case, Chicago, Lester LeVyn, Buffalo, and Ross Golden, New York

Drs Max Ritvo and David B Stearns, Boston, presented a paper on "Roentgen Diagnosis of Contusions of the Kidney" Discussed by Drs Edward L Jenkinson, Chicago, David B Stearns, Boston, Ross Golden, New York, and W T Clark, Janesville, Wis

Dr Lee A Hadley, Syracuse, N Y, read a paper on "Pathologic Conditions of the Spine Painful Disturbances of the Intervertebral Foramina" Discussed by Drs William E Chamberlain, Philadelphia, and D Y Keith, Louisville, Ky

THURSDAY, JUNE 10—AFTERNOON

Drs William Snow and Charles S B Cassasa, New York, presented a paper on "Obstructive Emphysema and Atelectasis in Influenza A New Approach" Discussed by Drs E G Galbraith, Toledo, Ohio, Le Roy Santé, St Louis, and Robert G Torrey, Philadelphia

An informal address was made by Dr Colin MacDonald, Melbourne, Australia, official representative of the Victoria Branch of the British Medical Association

Dr Howard P Doub, Detroit, read a paper on "The Roentgen Aspect of Sympathetic Neuroblastoma" Discussed by Drs E L Rypins, Bloomington, Ill, Colin MacDonald Melbourne, Australia, Ralph E Myers, Oklahoma City, and John T Murphy, Toledo, Ohio

The following papers were read as a symposium on "The Teaching of Radiology"

Dr Claude Moore, Washington, D C "A Survey of the Undergraduate Teaching of Radiology in the Medical Schools of the United States"

Dr Eugene P Pendergrass, Philadelphia "Experiences in Teaching Radiology to Undergraduate Students"

Dr B R Kirklin, Rochester, Minn "Graduate Education and Training of Radiologists"

These three papers were discussed by Drs J H J Upham, Columbus, Ohio, Merrill C Sosman, Boston, Fred J Hodges, Ann Arbor, Mich, Thomas Groover Washington, D C, Ross Golden, New York, Charles L Martin, Dallas, Texas, and Edward L Jenkinson, Chicago

Drs Walter L Mattick and Eugene M Burke, Buffalo, presented a paper on "Bronchus Carcinoma A Pathologic and Radiologic Consideration" Discussed by Drs Ralph E Myers, Oklahoma City, and Orville N Meland, Los Angeles

FRIDAY, JUNE 11—AFTERNOON

The following officers were elected chairman, Dr B R Kirklin, Rochester, Minn, vice chairman, Dr R G Taylor, Los Angeles, secretary, Dr John T Murphy, Toledo Ohio, executive committee Dr Edward L Jenkinson, Chicago, Dr Ross Golden, New York, and Dr B R Kirklin, Rochester, Minn, delegate, Dr Edward H Skinner, Kansas City Mo, alternate, Eugene P Pendergrass, Philadelphia

Dr Eugene V Powell, Temple, Texas, read a paper on "Roentgen Therapy of Acute Pneumonias" Discussed by Drs Fred M Hodges, Richmond, Va, and T J Curphey, New York

Drs Hugh F Hare and Nell Swinton, Boston, presented a paper on "Cancer of the Thyroid" Discussed by Drs Harold W Jacob, Pittsburgh, George Pfahler, Philadelphia, and Solomon Ginsburg, New York

Drs E A Merritt and R Rhett Rathbone, Washington, D C, presented a paper on "The Heavily Filtered Roentgen Treatment of Superficial Epitheliomas" Discussed by Drs Richard Dresser, Boston, John T Murphy, Toledo, Ohio, George Pfahler, Philadelphia, and Gisela von Postwik, Scranton, Pa

Dr Traian Leucutia, Detroit, read a paper on "The Value of Supervoltage Roentgen Therapy" Discussed by Drs Orville N Meland, Los Angeles, and D Y Keith, Louisville, Ky

Dr Byron Jackson, Scranton, Pa, presented a tribute to Dr Russell Boggs Radiologist, as follows

"After looking at these photographs and hearing these papers about these wonderful scientific instruments, it gives me some stimulation to tell you something about one of our pioneers. In a very few words, I will try to tell you a simple story about this man of whom you have all heard

"Thirty-seven years ago, after studying in Paris and Vienna and New York, Dr Herbert Russell Boggs began the practice of roentgenology in Pittsburgh. Dr Boggs was Pittsburgh's pioneer roentgenologist

"If you will just go back from these scientific instruments for a minute and visualize an old gas tube (we say old, of course), a static machine and a mechanical interrupter, and all the difficulties that came along with them, you will appreciate this pioneer

"Dr Boggs was born in Evans City, Pa, in 1873. He graduated from the Western University of Pennsylvania in 1897. He practiced medicine for a year or so and then went to Paris, where he studied in the University of St Louis, the Hospital of St Louis, and then to Vienna, at the University of Vienna, where he became interested in the newly discovered roentgen rays. He immediately went back home and began an exclusive practice of roentgenology

"He soon was connected with at least six hospitals in Pittsburgh or its vicinity, and these he gradually relinquished to other men whom he had taught as much as he knew about the work

"In Pennsylvania, we are particularly anxious to have you know about Dr Boggs because of one thing about him. He was very much interested in all the young men who were beginning the practice of roentgenology. He was very anxious to tell them everything that he had learned and to help them in every way he could to carry on. I happen to be one of those young men and, of course, more than anybody else here, probably appreciate what he did for us

Today, we still use positions that he taught us, that have not been improved on in any way. A month before he died—his death occurred the second day of June, 1922—he read a paper before the Academy of Medicine at Pittsburgh entitled "The Use of Radium in the Treatment of Epithelioma." That paper is just as fresh today and just as valuable today as it was the day it was written. There is nothing changed about it except our filtration which we use for radium, which, of course, he knew nothing about. His illustrations are just such illustrations as you saw today, his needles are placed in positions just as you saw them today

"This man was an indefatigable worker and a prolific writer, which he easily could be because he was making new discoveries every day. He was one of the charter members of the American Roentgen Ray Society and he was instrumental in starting with several other men, the Central Pennsylvania Roentgen Ray Society, whose primary object was to bring men in from the outlying districts of Pittsburgh and Philadelphia so that they might get a chance to express themselves—self expression, I suppose we would say

"We feel in Pennsylvania at least that we are greatly indebted to the American Medical Association for giving us the Russell Boggs Memorial Lecture, by which we can honor this pioneer radiologist

The following papers were read as a symposium on "Carcinoma of the Breast"

Drs George E Pfahler and Jacob H Vastine, Philadelphia "The Value of Preoperative and Postoperative Irradiation in Carcinoma of the Breast" (Russell Boggs Memorial Lecture)

Dr U V Portmann, Cleveland "A Classification for Carcinoma of the Breast with Reference to Statistical Studies and Indications for Therapeutic Procedures"

Drs Harriet C McIntosh and Sophie Spitz, New York "Clinical Significance of Lung Changes Following Roentgen Irradiation for Mammary Cancer"

These three papers were discussed by Drs Frank E Adair, New York, and E E Downs Woodbury, N J

THE SCIENTIFIC EXHIBIT

The Scientific Exhibit at the Atlantic City session was characterized by the high caliber of exhibits presented. There were 254 exhibits in all, of which 219 were presented by individual exhibitors, twenty-five by government and national organizations, five by councils and bureaus from the American Medical Association headquarters, and two special exhibits subsidized by the Board of Trustees.

The special exhibit on anesthesia was presented under the auspices of a committee composed of D Chester Brown, chairman, Danbury, Conn., Frank H. Lahey, Boston, and Paul Nicholas Leech, Chicago, assisted by members of the Associated Anesthetists of the United States and Canada, the American Society of Anesthetists, and the American Society of Regional Anesthesia. In addition to continuous demonstrations by a competent corps of demonstrators, there were talks and motion pictures throughout the week in an area adjoining the exhibits. A pamphlet describing the exhibit was distributed.

The special exhibit on fractures was presented under the auspices of a committee composed of Kellogg Speed, chairman, Chicago, Frank D. Dickson, Kansas City, Mo., and Walter Estell Lee, Philadelphia, assisted by an advisory committee composed of Isidore Cohn, New Orleans, H. Earle Conwell, Birmingham, Ala., Frederic J. Cotton, Boston, Richard B. Dillehunt, Portland, Ore., Eldridge L. Eliason, Philadelphia, Leo Eloesser, San Francisco, George W. Hawley, Bridgeport, Conn., Melvin S. Henderson, Rochester, Minn., James M.

Hitzrot, New York, William L. Keller, Washington D. C., Roy D. McClure, Detroit, Frank R. Ober, Boston, Dallas B. Phemister, Chicago, and J. Spencer Speed, Memphis, Tenn. More than fifty physicians from various parts of the country assisted with the demonstrations. Acknowledgment is made to the Surgeon General of the United States Army, Major A. S. Dabney, Major W. W. McCaw, soldiers from the Walter Reed Hospital, Dr. James H. Mason III of Atlantic City, and Mrs. Mildred Jones and Miss Flora Keats, nurses from the Atlantic City Hospital, for the very efficient service which they rendered in connection with the fracture exhibit. Appreciation is also expressed to the management of the Atlantic City Hospital for its cooperation.

Other features of the Atlantic City session included a symposium on pneumonia by the Section on the Practice of Medicine, a symposium on heart disease composed of twenty-five exhibits presented in cooperation with the American Heart Association, and motion picture programs by the Section on Obstetrics, Gynecology and Abdominal Surgery, by the Section on Ophthalmology, and by the Section on Orthopedic Surgery shown in spaces adjoining the exhibits of those sections.

An endeavor was made to correlate the exhibits with papers read before the various sections of the Scientific Assembly, with the result that fifty papers were accompanied by material in the Scientific Exhibit.

REPORT OF THE COMMITTEE ON AWARDS

The Committee on Awards made the following report:

CLASS I

(Awards in Class I are made for exhibits of individual investigation, which are judged on the basis of originality and excellence of presentation.)

The GOLD MEDAL to Leonard G. Rowntree, Arthur Stenberg, N. H. Einhorn, J. H. Clark, George M. Dorrance and E. F. Ciccone, Philadelphia Institute for Medical Research, Laboratory of Philadelphia General Hospital and American Oncologic Hospital, Philadelphia, and A. M. Hanson, Faribault, Minn., for exhibit illustrating original investigation on normal and abnormal growth associated with the development of sarcoma in albino rats from the ingestion of a crude wheat germ oil made by ether extraction.

The SILVER MEDAL to Eben J. Carey, Department of Anatomy, Marquette University School of Medicine, Milwaukee, for exhibit illustrating original investigation on intrinsic wave mechanics of the nervous and muscular systems.

The BRONZE MEDAL to Louis Gross, Mount Sinai Hospital, New York, for an exhibit illustrating experimental studies of the blood supply to the heart in relation to coronary sclerosis.

CERTIFICATES OF MERIT, Class I, are awarded to the following (alphabetically arranged):

Lester R. Dragstedt and John Van Prohaska, Department of Surgery, University of Chicago Clinics, Chicago, for exhibit of original work on lipocaic, a new pancreas hormone.

Harry Goldblatt, Department of Pathology, Western Reserve University School of Medicine, Cleveland, for exhibit illustrating results of work on experimental hypertension.

Nelse F. Ockerblad and Hjalmar E. Carlson, Department of Urology, University of Kansas School of Medicine, Kansas City, Kan., for exhibit illustrating the distribution of urethral pain.

Isaac Schour, University of Illinois, Chicago, for exhibit illustrating tooth-ring analysis.

Charles S. Venable, Walter G. Stuck and Asa Beach, San Antonio, Texas, for exhibit illustrating the effect of electrolysis in osteosynthesis with metals.

In addition, the following exhibits are deemed worthy of honorable mention (alphabetically arranged):

That of Elmer L. De Gown and W. L. Randall, Department of Internal Medicine, State University of Iowa, on renal damage from blood transfusion.

That of Deryl Hart, Duke Hospital, Durham, N. C., on sterilization of the air in the operating room with bactericidal radiant energy.

That of Herbert L. Johnson, Boston, illustrating absorbable sutures and insulating patches made from human and bovine fetal membranes.

That of Virgil H. Moon, David R. Morgan and Marshall M. Lieber, Department of Pathology, Jefferson Medical College, Philadelphia, illustrating shock, its pathology and sequelae.

That of J. W. Schereschewsky, United States Public Health Service and Harvard Medical School, Boston, on carcinogenic compounds and lung tumors in mice.

That of Marvin R. Thompson, University of Maryland, Baltimore, on ergot and its active principles.

That of W. F. Wells and Mildred Weeks Wells, Harvard School of Public Health, Boston, on air-borne infection.

Particular commendation is made of the personal demonstration by Edward C. Rosenow, Mayo Foundation, Rochester, Minn., of his exhibit on the relation of streptococci to the viruses of encephalitis and poliomyelitis.

CLASS II

(Awards in Class II are made for exhibits which do not exemplify purely experimental studies and which are judged on the basis of excellence of presentation.)

The GOLD MEDAL to M. S. Henderson, H. W. Meyerding, R. K. Ghormley and H. B. Macey, Mayo Clinic, Rochester, Minn., for excellence of presentation of exhibit illustrating fractures, a potential source of deformity and disability.

The SILVER MEDAL to Frank W. Hartman, Henry Ford Hospital, Detroit, for exhibit on oxygen therapy with the use of liquid oxygen and air, a new efficient low cost oxygen tent.

The BRONZE MEDAL to Franklin F. Snyder and Morris Rosenfeld, Johns Hopkins Hospital, Baltimore, for exhibit illustrating intra-uterine respiration of the fetus and its relation to respiratory failure at birth.

CERTIFICATES OF MERIT, Class II, are awarded to the following (alphabetically arranged):

Charles A. Doan, Bruce K. Wiseman and Carl G. Moore, Ohio State University, Columbus, for exhibit illustrating the pathologic physiology, differential diagnosis and treatment of hematologic dyscrasias.

N Frederick Hicken and R Russell Best, Omaha, for exhibit on mammography, the roentgenographic diagnosis of breast tumors by contrast visualization

Hugo Roesler, Temple University School of Medicine, Philadelphia, for exhibit illustrating the correlation between anatomy, pathology and roentgenology of the cardiovascular system

M C Wintermütz, Yale University School of Medicine, New Haven, Conn, for exhibit illustrating studies on the pathology of arteriosclerosis

E E Woldman and V C Rowland, Cleveland, for exhibit illustrating the treatment of peptic ulcer by continuous aluminum hydroxide drip

In addition, the following exhibits are deemed worthy of HONORABLE MENTION (alphabetically arranged)

That of Rhoda W Benham and Edward D De Lamater, New York, on the pathogenic fungi

That of A E Briley, P J Leinfelder and C S O'Brien, University Hospitals, Iowa City, on orbital tumors

That of William Dameshek and Henry H Henstell, Boston, on biopsy of sternal marrow

That of Rigney D'Aunoy and Emmerich Von Haam, Department of Pathology, Louisiana State University Medical Center, New Orleans, a clinical and pathologic study

That of Robert Greenblatt and Everett S Sanderson, University of Georgia Medical College, Augusta, on bacillary antigen for intracutaneous test in the diagnosis of chancroid

That of R H Flocks, Department of Urology, State University of Iowa, College of Medicine, Iowa City, on the arterial distribution within the prostate gland—its role in prostatic resection

That of Clayton J Lundy, Rush Medical College, Chicago, on the mechanism and electrocardiographic registration of the heart in health and disease

That of John S Lundy, L H Mousel E B Tuohy and R C Adams, Mayo Clinic, Rochester, Minn, on the technic of regional anesthesia

That of Abraham Myerson, Julius Loman, Max Rinkel, Max Ritvo and J G Schube, Research Laboratory, Boston State Hospital, Boston, on autonomic pharmacology of the human being

That of John T Talbott, Massachusetts General Hospital, Boston, on clinical and laboratory studies on patients with gout

Special commendation is made of the following exhibits

That of Jesse G M Bullock, Clare Wilcox, Benjamin Wolfman, Herman D Ratish and Evelyn Greenbaum, New York, on management of the pneumonias

That of Russell L Cecil Louis I Dublin and Donald B Armstrong, Metropolitan Life Insurance Company, New York, on pneumonia control

That of Elliott C Cutler and Robert Zollinger, Peter Bent Brigham Hospital, Boston, on the technic of common surgical procedures

That of Sigmund Epstein, New York, illustrating the crutch in art through forty centuries

GROUP EXHIBITS

A SPECIAL CERTIFICATE OF MERIT is awarded to the group exhibit of the Lahey Clinic, Boston. The committee suggests that hereafter group exhibits be excluded from the Scientific Exhibit

EDUCATIONAL CLASSIFICATION

A SPECIAL CERTIFICATE OF MERIT is awarded to the United States Navy, Medical Department, Washington, D C, for its exhibit on naval medical activity pertaining to preventive and industrial medicine and public health

The committee commends the educational exhibits on cancer, syphilis and tuberculosis

SPECIAL EXHIBITS (SUBSIDIZED)

The Committee on Awards commends particularly the special exhibits on anesthesia and fractures sponsored by the American Medical Association, and those of the various councils and bureaus of the Association

The committee extends its commendation to the many individual exhibitors who have developed exhibits from their own resources and have spared no effort to explain and demonstrate their exhibits

The committee emphasizes that the members and Fellows of the American Medical Association owe grateful appreciation to the Committee on Scientific Exhibit of the Board of Trustees and to Dr Thomas G Hull, the executive in charge of the arrangements of the Scientific Exhibit

LUDVIG HEKTOEN, Chairman, Chicago
ARTHUR J BEDELL, Albany, N Y
FRANK K BOLAND, Atlanta, Ga
RUSSELL L HADEN, Cleveland
JAMES D TRASK, New Haven, Conn

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES NEW HOSPITALS EDUCATION AND PUBLIC HEALTH)

ARKANSAS

Personal—Dr Edward W Pillstrom has been appointed health officer at Coal Hill—Dr James T Tipton, Mountain Home, has celebrated the completion of fifty years in the practice of medicine—Dr Robert H Johnson, Clarksville has been appointed health officer of Johnson County

CALIFORNIA

Personal—Dr John M Kirby, Bakersfield, has been placed in charge of a newly created health unit in Monterey County—Dr Edwin Vincent Askey has resigned as secretary-treasurer of the Los Angeles County Medical Association, an office he had held since 1934. Dr Askey was recently elected to the board of education. He has been succeeded by Dr George D Maner as secretary of the society

Society News—Dr Arthur Elmer Belt, Los Angeles, addressed the San Diego County Medical Society, May 11, on "Fever Therapy in Gonococcal Infections". Dr Frank Krusen, Rochester, Minn, addressed the society, June 17, on "Present Status of Physical Therapy"—Dr Willard J Stone, Pasadena, discussed "Bright's Disease and Arterial Hypertension" before the Hollywood Academy of Medicine, May 20—The Alameda County Medical Association was addressed, June 21, by Drs Clifford W Mack, Livermore, on "Insulin Shock in Dementia Praecox", John A Dougherty, Oakland, "Urinary Antiseptics", Lester B Lawrence, Oakland "Management of Acute Head Injuries", and Thomas Floyd Bell, Oakland, "Cervicitis and Vaginitis"

COLORADO

Society News—Dr Herman C Graves, Grand Junction, was the principal speaker before the Delta County Medical Society, May 28, on albuminuria—At a meeting of the Fremont County Medical Society in Canon City, June 11, Dr Vera Henly Jones, Denver, showed a motion picture entitled "After-Care of Poliomyelitis"

New Committee on Syphilis—A continuing committee on the control of syphilis has been appointed for the Colorado State Medical Society, consisting of six members to serve overlapping three year terms. They are Drs Edward R Mugrage, chairman, and Robert S Liggett, Denver, three years, Gerald M Frumess, Denver and Charles H Boissevain, Colorado Springs two years, George M Myers and Julius L Rosenbloom, Pueblo, one year

CONNECTICUT

Personal—Dr Edward P Kemp has been appointed health officer of Fairfield for the unexpired term of Dr Laurence E Poole, who recently resigned on account of ill health

Cancer Fund of \$10,000,000 Given to Yale—The Jane Coffin Childs Memorial Fund for Scientific Research, to be devoted to research on cancer, has been established through a gift of \$10,000,000 to Yale University, New Haven, according to the *New York Times*. The donor of the fund was not announced by the university, but the report stated that Starling

W Childs, New York investment banker, had set up the endowment. The deed of gift provides that if, and when, the cancer problem is solved, the foundation is to devote its time to unsolved medical problems in other fields of science. Under the deed the foundation, which is expected to cooperate closely with Yale University School of Medicine, will be administered by a board of managers advised by a board of scientific advisers. The latter board will include Dr Stanhope Bayne-Jones, Rudolph J Anderson, Ph D, Drs Ross G Harrison and Milton C Winternitz, all of Yale, and Dr Francis Peyton Rous of the Rockefeller Institute for Medical Research, New York.

FLORIDA

New Officers of State Board—Dr John M Mann, Lake Butler, formerly state senator, was elected president of the State Board of Medical Examiners of Florida at its annual meeting, June 14, succeeding Dr James E Crump, Winter Haven. Dr Julius C Davis, Quincy, formerly president of the state medical association, was chosen vice president, and Dr Wilham M Rowlett, Tampa, was reelected secretary.

GEORGIA

Hospital News—The state tuberculosis sanatorium at Alto was to be placed under the management of the state board of health, July 1, in accordance with a recent act of the legislature.

Awards Presented During Annual Meeting—The name of Dr James L Campbell, professor of clinical surgery, Emory University School of Medicine, Atlanta, will be inscribed on the L G Hardman Loving Cup, it was announced at the recent annual meeting of the Medical Association of Georgia. This honor is awarded annually to the physician considered to have rendered the most distinguished medical service during the previous year. The cup was given to the state medical association by the late Governor Hardman, who was a member of the association for more than fifty years. Dr Campbell graduated from Emory in 1893. Dr Charles Glenville Giddings Jr, assistant professor of clinical medicine at the university, was presented with the Crawford W Long Award for the best research work in the state during 1935-1936.

IDAHO

The Annual Spring Meeting—The South Side Medical Society held its annual spring meeting in Twin Falls May 15. The scientific program was presented by four San Francisco physicians. Drs Frederic C Bost, on 'Treatment of Fractures of the Femur', Robert G Craig, 'Common Gynecological Problems', Clark M Johnson, 'Urinary Infections and Obstructions,' and Edmund W Butler, 'Injuries of the Chest'.

ILLINOIS

Society News—Dr Richard H Jaffe, Chicago, discussed 'Tumors and Tumor-like Lesions of the Breast' before the Sangamon County Medical Society, Springfield May 6—Dr Julius Steinfield, Peoria, discussed 'The Principles and Medical Value of Psychoanalysis' before the Peoria City Medical Society, May 4.

The New Marriage License Law About Venereal Disease—Applicants for licenses to marry must present physicians' certificates and laboratory affidavits attesting freedom from venereal disease, in accordance with a new law which went into effect July 1. The laboratory tests may be taken without cost at city or state health department laboratories. The certificate must be made within fifteen days of the application for a license, which, when issued, shall be good for only thirty days. The law provides a \$100 fine or a six months jail sentence for any county clerk issuing a marriage license without the required medical certificates or for any physician or laboratory technician found guilty of falsifying the affidavits. A similar fine or a three months jail sentence is provided for any marriage applicant violating the new law. Similar laws are in effect in Connecticut, Montana and Oregon while Alabama, Louisiana, North Dakota and Wyoming demand certificates from men alone. Wisconsin has also required certificates from men but now has awaiting the governor's signature a bill which will bring women under the same provisions.

Chicago

Personal—Dr Thomas P Foley has been appointed a member of the medical examining committee of the Illinois State Department of Registration. Dr Foley was secretary of the Chicago Medical Society from 1932 to 1934 and president in 1936. He has been chairman of the department of medicine at Oak Park Hospital since 1929—Maud Sive AB, asso-

ciate professor of pathology, school of medicine at the University of Chicago, received the honorary degree of doctor of science from Brown University, Providence, R I, June 21.

Work Begins on the New Wesley Hospital—Construction of a new building for Wesley Memorial Hospital began June 19 when Mr George H Jones turned the first spadeful of earth on the site at Superior Street and Fairbanks Court. Mr Jones provided the funds for the building, which will cost about \$2,000,000. The main portion of the building will be fifteen stories high, with a tower section extending four stories higher. The first floor will be used for executive offices, staff and lecture rooms, doctors' lounge, the admission department, two emergency operating rooms and a necropsy amphitheater. On the second floor will be the physical therapy and x ray departments, medical library and records, kitchens, dining rooms and cafeteria. The third floor will comprise a diagnostic unit, a general waiting room and a special department for eye, ear, nose and throat. The fourth floor will have fourteen operating rooms air conditioned all the year. The other floors will contain beds arranged in wards and in individual rooms. The entire twelfth floor will be devoted to obstetrics and be completely air conditioned. The seventeenth floor of the tower will

Proposed new Wesley Hospital

be used for a lounge. One floor of the new structure will be given over to adolescents. The building, which has been designed so that sunlight will reach every patient sometime during the day will accommodate 420 beds. There will be 140 free beds available for teaching, while facilities for all classes of patients will be provided. Seventy rooms will be available for persons of moderate means. The present Wesley Memorial Hospital has occupied a site at Twenty-Fifth and Dearborn streets since 1888. In 1914 it was endowed with \$1,000,000 for teaching purposes by the late James Deering in memory of his father and sister, William Deering and Abby Deering Howe. Under the terms of the deed the staff of the hospital must be chosen from Northwestern University Medical School. The new building is expected to be ready for occupancy Dec 25 1938, the fiftieth anniversary of the first admission of a patient to Wesley.

INDIANA

Hospital News—The new \$100,000 Michigan City Sanatorium, Michigan City, has been opened to patients.

New Clinical Building at University—The cornerstone of a new clinical building at the University of Indiana School of Medicine, Indianapolis, was laid, May 12, by William Lowe Bryan, president of the university. The speakers included Dr Frank C Mann, Rochester, Minn. Dr Nicholson J Eastman, Baltimore, and Frederic R Henshaw D D S, of the

university's school of dentistry The new six story building, which will be completed in the fall, will cost about \$750,000 when fully equipped

Personal—A bronze plaque has been placed in the reception hall of St Joseph Hospital, Fort Wayne, in memory of Dr Maurice I Rosenthal, first president of the hospital staff, who died Dec 24, 1935.—Dr Herman G Morgan has been appointed president of the Citizens' Safety Committee, Indianapolis

IOWA

Rocky Mountain Spotted Fever—Three probable cases of Rocky Mountain spotted fever, all in the same rural household, were reported in Clarke County, June 9, according to the state health department One of the children concerned, a girl of 3 years, died June 10, it was stated This disease had not been reported from Clarke County, which is in south central Iowa, since four years ago, when two cases occurred and a third probable case resulted fatally A child from Jackson County in eastern Iowa, who was at the time of this report a patient at the Children's Hospital, Iowa City, is the fourth person known to have had the disease thus far this year

Twin Lakes District Meeting—The dry diagnostic clinic and fifteenth annual assembly of the Twin Lakes District Medical Society was held at Burns' Alhambra Pavilion, Twin Lakes, Rockwell City, June 17 Dr Austin A Hayden, Chicago, addressed the meeting on "The Science and Art of Medicine" Others on the program included Drs Carl H Gellenthien Valmora, N M, John W Duncan, Omaha, Elmer G Wakefield, Rochester, Minn, Garwood C Richardson, Chicago, and Peter T Bohan Kansas City, Mo Clinics in diseases of the chest, surgery, functional disorders of the colon, obstetrics and general medicine were included on the program

KENTUCKY

School for Health Officers—The state department of health conducted its annual school for health officers, May 10-12, in Louisville at the Brown Hotel The program placed special emphasis on tuberculosis, malaria, sanitation and milk control Among the lecturers were Drs James P Leake and Robert Olesen and Mr Leslie Frank, senior sanitary engineer all of the U S Public Health Service, Drs Mark F Boyd of the International Health Board, Rockefeller Foundation, and Horton R Casparis, Nashville, Tenn, and Mr R J Morton, Nashville

LOUISIANA

Civic Cup Awarded to Physician—Dr Lambert O Clark Lafayette, was recently presented with the 1936 civic award for outstanding service to the community The cup is sponsored by the Young Men's Business Club Dr Clark, who is 57 years of age, graduated from Tulane University of Louisiana School of Medicine, New Orleans, in 1905

Society News—The Orleans Parish Medical Society held a clinical meeting at the U S Marine Hospital, New Orleans, June 28, speakers were Drs Richey L Waugh, "Rupture of the Biceps Brachii", Joseph G Pasternack, "Pathologic Physiology and Pathology of Experimental Gas Gangrene," and Mr Howard N Old, sanitary engineer, "Public Health Aspects of the Recent Flood" The society was addressed, June 14, among others, by Drs Reynoldo Dos Santos, professor of surgery, University of Lisbon, Portugal, on arteriography, and Rudolph Matas, New Orleans, vascular surgery

MAINE

Ordinance Requires Physical Examination of Food Handlers—All proprietors of eating and drinking establishments in Bangor will be required to obtain a certificate of good health from applicants for positions before they are accepted, in accordance with an ordinance recently adopted The ordinance further provides that medical inspections will be made twice a year The certificate must be from a reputable physician stating that the applicant is free from any communicable disease The ordinance requires that the examination be complete enough to determine the presence or absence of any exanthematous disease and oral or nasal infections and that it include the collection of material for laboratory examination if infections are suspected On suspicion of tuberculous infection of any applicant, a thorough physical examination of the lungs will be made and laboratory specimens will be collected and forwarded to the state laboratory for examination All persons will be questioned as to a history of typhoid Certificates will be made on forms approved by and filed with the city health officer

MASSACHUSETTS

State Medical Election—Dr Channing Frothingham, Boston, was elected president of the Massachusetts Medical Society at its annual meeting in Boston, June 2 Dr Walter G Phippen, Salem, was chosen vice president and Dr Alexander S Begg, Boston, was reelected secretary

Anatomist Honored on Ninetieth Birthday—Edward Laurens Mark, Ph D, Hersey professor of anatomy, emeritus, Harvard University, Boston, was honored on his ninetieth birthday, May 30, when a bound volume of letters, written by former students and friends, was presented to him Dr Mark graduated at the University of Michigan in 1871 and received his degree of doctor of philosophy from the University of Leipzig in 1876 He served as instructor in mathematics, University of Michigan, and as astronomer of the U S Northwest Boundary Survey In 1877 he joined the faculty at Harvard, serving from 1885 to 1921 as professor of anatomy He was director of the Zoological Laboratory at Harvard from 1900 to 1921 and director of the Bermuda Biological Station for Research from 1903 to 1931 He was delegate from the United States to the fourth International Zoological Congress in 1898 He is a member of many scientific societies and has written numerous articles and textbooks

MICHIGAN

Society News—Dr Francis B Fralick Ann Arbor, discussed eye conditions found in general practice before the Calhoun County Medical Society, June 1, in Battle Creek.—At a recent meeting of the East Side Physicians Association, Detroit the speakers included Dr Ira G Downer on "Diagnosis and Treatment of Subacromial Bursitis with a Report of Seven Cases"—Dr Robert L Schaefer, Detroit addressed the Shiawassee County Medical Society, May 20, on "Clinical Evaluation of the Anterior Pituitary-like Sex Hormone"—Mr Milton Simpson, Kalamazoo, addressed the Kalamazoo Academy of Medicine, June 15, on "Literature's Contribution to the Physician"

MINNESOTA

Grant for Research in Biology—The Rockefeller Foundation has given \$36,000 to the University of Minnesota for research in biology and medicine The project will involve the construction of high voltage equipment in the physics laboratory, consisting principally of a giant Van de Graff generator capable of producing from six to eight million volts of electricity

Chemical Group Offers Medical Program—The fourteenth National Colloid Symposium, sponsored by the American Chemical Society and the National Research Council held a meeting at the Mayo Clinic, Rochester, June 12 The speakers included

Wendell M Stanley Ph D Princeton N J Rockefeller Institute for Medical Research Virus Proteins A New Group of Macromolecules
Dr Maurice B Visserer Minneapolis Influence of Various Ions upon the Movement of Materials Across Living Membranes
Dr Hugh R Bult and Ansel B Keys Ph D Rochester Osmometric Study of Gum Acacia Solutions Used for Intravenous Injection
Drs Arthur H Sanford and Douglas B Roxburgh Rochester Effect of Protein Type and Concentration on the Precipitation of Gold Solutions

Personal—Dr A Dair Haskell has been elected mayor of Alexandria.—Dr David M Parker, who recently opened offices for practice in Mountain Iron, has been appointed village health officer—Villanova College, Villanova, Pa conferred the honorary degree of doctor of laws on Drs Charles H and William J Mayo, Rochester, at its commencement exercises, June 3.—Dr Francis E Harrington, city health commissioner, has been appointed acting superintendent of the Minneapolis General Hospital—Dr Alex G Berger has been appointed chief quarantine officer of Minneapolis, succeeding Dr Ragnar T Westman, resigned.—Dr Henry C Cooney, medical director of Northwestern Hospital, Princeton, was guest of honor at a dinner, April 19 in celebration of his birthday Dr Cooney graduated from the University of Illinois College of Medicine in 1887

MISSOURI

Fifty Years of Practice—Dr Linn J Schofield was the guest of honor at a meeting of the Johnson County Medical Society, June 2 in celebration of his completion of fifty years of practice in Warrensburg Dr Schofield graduated from the University of Louisville Medical Department in 1887 He is secretary of the city board of health and formerly served as county health officer and as president of the county medical society in 1917

MONTANA

State Medical Meeting at Great Falls—The Montana State Medical Association will hold its annual convention at the Heisey Memorial, Great Falls, July 13-14, under the presidency of Dr John A Evert, Glendive. Hon Julius J Wuertner, mayor of Great Falls, will open the scientific session Tuesday afternoon with an address of welcome. Other speakers on the program will include

Dr Henry Schmitz Chicago, Treatment of Uterine Myomas
Dr Roland G Scherer Bozeman Conservative Renal Surgery
Dr Russell B Richardson Great Falls Fractures of Os Calcis
Dr Ferdinand R Schemm, Great Falls Fluid Intake in Edematous Patients
Dr Jack K Colman Butte, Paralysis of the Peripheral Nerves of the Upper Extremity
Dr Fred F Attix Lewiston Massive Purulent Pericarditis
Dr John H J Upham Columbus Ohio President American Medical Association Heart Disease in Middle Life
Dr Herbert H James Butte Cancer and Its Treatment with Radium
Dr Ernest M Hammes St Paul Psychosis Associated with the Involutional Period
Dr Jessie M Bierman Helena, Nephritis in Children

Dr Upham will also address the annual banquet Wednesday evening on "Changing Times in Medicine" and Dr Anton J Carlson, Chicago, will speak on "Black Oxen and Togenburg Goats." The Cascade County Medical Association will be host to the session.

NEW HAMPSHIRE

Trailer Regulations—New Hampshire has adopted sanitary regulations covering trailer coaches and trailer camps. The rules relate to equipment of the coaches, including certain requirements for proper care and disposal of wastes. They require that coaches be screened and kept free from accumulations of refuse and that receptacles be cleaned and disinfected each time they are emptied. All trailer coaches are to be open to inspection by agents of the state board of health at all reasonable hours and it is required that, in the event of any illness suspected of being communicable, a physician be called promptly and the health officer notified if the illness is found to be communicable. Trailer camps and parks are also required to maintain certain standards. Water must be supplied from faucets and provision must be made for proper disposal of wastes. Camp sites must provide space of at least 20 by 35 feet for each trailer, and no greater number of trailer parties are to be allowed than the space can accommodate. Supplementing the regulations, the board of health also issued advice concerning water and milk supplies. Tanks should be filled only from sources of supply under inspection or, if it is necessary to resort to wells or springs, such water should be disinfected with hypochlorite solution.

NEW YORK

Society News—Dr Eldridge H Campbell Jr, Albany, addressed the Medical Society of the County of Albany, June 23, on "Diagnosis and Treatment of Brain Tumors."—At a meeting of the Saratoga County Medical Society at the Saratoga Spa, June 3, the speakers were Drs Leroy W Hubbard, Mount Vernon, on "Polymyelitis—Its Recognition and Treatment", John D Currence, New York, "Hydrotherapeutic Treatment of Arthritis and Related Conditions", Paul Klemperer, New York, "Vascular Diseases of the Kidney," and Herman O Mosenthal, New York, "Prevention and Treatment of Uremia."—Dr George H Ramsey, director of communicable diseases, state department of health, Albany, addressed the quarterly meeting of the Suffolk County Medical Society, Huntington, April 28, on "Syphilis as a Public Health Problem."

New York City

Annual Library Report—The Library of the Medical Society of the County of Kings and the Academy of Medicine of Brooklyn reports that the number of readers using the library decreased 5 per cent in 1936 from the number reported in 1935. The report attributes the difference to improving economic conditions reflected in less leisure for reading. In 1936 the number of readers was 15,134, the number of books consulted in the library 57,623, and the number taken for home use 12,295. The library added 775 volumes of new publications to its shelves during the year, partly by purchase and partly by donations of books received for review by the *New York State Journal of Medicine* and the *Medical Times and Long Island Medical Journal*. A total of 1,590 current periodicals and serial publications are now on file in the library, an increase of sixty-six over the previous year. It is estimated that the library now contains about 140,122 bound and unbound volumes.

The Annual Graduate Fortnight—The tenth annual Graduate Fortnight presented by the New York Academy of Medicine will be held, November 1-12, on "Medical and Surgical Disorders of the Urinary Tract." Twenty-one hospitals will present coordinated clinics and demonstrations during the days, and a group of lectures will be presented at the academy building in the evenings. The speakers at these sessions will be

Dr Alfred N Richards Philadelphia Physiology of the Kidney
Donald D Van Slyke, Sc D New York Tests for Kidney Function.
Dr Dana W Atchley New York Edema and Its Treatment
Dr Arthur M Fishberg New York Uremia and Pathology of Kidney Function
Dr Milton C Winternitz New Haven Conn Pathology of Vascular Disease
Dr George Bachr New York The Pathology of Nephritis
Dr Robert F Loeb New York Clinical Aspects of Nephritis
Dr Irvine H Page New York Nature of Hypertension
Dr Herman O Mosenthal New York Clinical Aspects of Hypertension Including Malignant Hypertension
Dr George J Heuer New York Evaluation of the Surgical Treatment of Hypertension
Dr Albert A Epstein New York The Nephroses
Dr William W Herrick New York Vascular and Renal Complications of Pregnancy
Dr Karl A Menninger Topeka Kan Physiologic Factors in Hypertension
Dr William F Braasch Rochester Minn Pathogenesis and Treatment of Renal Infections
Dr Hugh Cabot Rochester Minn Renal and Perirenal Infections
Dr Linwood D Keyser Roanoke Va Calculus Disease Formation of Stones
Dr Henry G Bugbee, New York Clinical Aspects of Calculus Disease
Dr J Bentley Squier New York Hydronephrosis and Pyonephrosis
Dr John D Lytle New York Bright's Disease in Children
Dr Meredith F Campbell New York, Common Urologic Diseases in Children
Dr Benjamin S Barringer New York Radiotherapy of Tumors of the Urinary Tract
Dr Archie L Dean Jr New York Tumors of the Kidney and Ureter
Dr Edwin Beer New York Tumors of the Urinary Bladder
Dr William E Lower Cleveland Pathologic Physiology of Bladder Neck Obstruction
Dr Joseph F McCarthy New York Transurethral Resection of Bladder Neck Obstruction
Dr Hugh H Young Baltimore, Surgical Treatment of Obstructions at the Neck of the Bladder

An exhibit of books and of pathologic and research material will be presented, with demonstrations at regular intervals.

NORTH CAROLINA

Changes in Staff of State Board of Health—Dr John W Roy Norton, Raleigh, has recently been made assistant director of the division of preventive medicine in the state board of health, succeeding Dr Thomas C Worth. Dr Robert L Robinson, Raleigh, has recently been added to the staff of the division of industrial hygiene, and Dr George M Leiby was appointed during the past year as consultant in venereal disease control.

Special Society Elections—Dr Malcolm T Foster, Fayetteville, was elected president of the North Carolina Public Health Association at the recent annual meeting in Winston-Salem, Dr Joseph A Morris, Oxford, vice president, and Dr Avon H Elliot, Wilmington, secretary.—Dr Harry L Johnson, Hickory was elected president of the North Carolina Hospital Association at the annual meeting in Raleigh in conjunction with the hospital associations of Virginia and South Carolina.—Dr Robert P Noble Raleigh, was made president of the North Carolina Radiological Association at its annual meeting in Winston-Salem in May, during the meeting of the Medical Society of the State of North Carolina.

OHIO

University News—The University of Cincinnati College of Medicine announces a gift of \$4,000 to establish a laboratory for research on the effect of diet in nervous diseases. Drs Tom D Spies, associate professor of medicine, and Charles D Aring, instructor in medicine, will be in charge of the laboratory. The gift was made by Mr William J Shroder and his sisters in honor of their parents, Judge and Mrs Jacob Shroder, whose name the laboratory will bear.

OREGON

Plague Infection in Oregon—Tissue taken from a ground squirrel found dead on a ranch five miles northeast of Enterprise, Walla Walla County, was found to be plague infected, according to *Public Health Reports*, June 11.

Personal—Dr R E Lee Steiner has resigned as superintendent of the Oregon State Hospital, Salem, after thirty years in the position. He was succeeded July 1 by Dr John C Evans, assistant superintendent for many years.—Dr Harold M Erickson, The Dalles has been appointed health officer of The Dalles and Wasco County.

PENNSYLVANIA

Society News—Dr Francis A Faught, Philadelphia, addressed the Northampton County Medical Society, Easton, May 21, on periodic health examinations.—Drs William W G MacLachlan and John P Griffith, Pittsburgh, conducted medical and surgical clinics, respectively, at a meeting of the Cambria County Medical Society, Johnstown, June 3.—Dr Gabriel Tucker, Philadelphia, addressed the Washington County Medical Society, Washington, June 23, on "Cancer of the Lower Respiratory Tract"—The Lycoming County Medical Society held an all day cancer meeting June 18 at the Williamsport Hospital. Dr Samuel J Waterworth, Clearfield, spoke on methods of diagnosis, Dr George E Pfahler, Philadelphia, on "Radium and X-Rays in Treatment of Cancer," and Dr W Wayne Babcock, Philadelphia, "Surgery of Cancer." Dr Babcock also addressed an evening session on "The Problem of Eradicating Cancer and Associated Diseases"

Philadelphia

Faculty Changes at Jefferson—Among appointments and promotions on the faculty of Jefferson Medical College during the year just passed were the following

Dr John F Corby professor of military science and tactics
Dr Henry K Mohler clinical professor of therapeutics
Dr Baldwin L Keyes clinical professor of psychiatry
Dr Willard H Kinney clinical professor of genito urinary surgery
Dr Samuel A Loewenberg clinical professor of medicine
William A Kreidler Ph D associate professor of bacteriology
Dr J Hall Allen assistant professor of proctology
Dr Norman M MacNeill assistant professor of pediatrics
Dr William J Harrison assistant professor of ophthalmology
Dr Sidney L Olsho assistant professor of ophthalmology

Dr Hatfield Receives Trudeau Medal—Dr Charles J Hatfield, associate director of the Henry Phipps Institute of the University of Pennsylvania, received the Trudeau Medal awarded by the National Tuberculosis Association at its annual meeting in Milwaukee, May 31-June 3. Dr Hatfield, who graduated from the University of Pennsylvania School of Medicine in 1900, has been engaged in tuberculosis work for many years. He was managing director of the National Tuberculosis Association from 1914 to 1922, was president in 1924 and is now secretary. He has also been president of the Pennsylvania Tuberculosis Society and is at present a director of that society.

SOUTH CAROLINA

Veteran Physicians Honored—The Spartanburg County Medical Society at a meeting at the Spartanburg Country Club, May 31, honored three physicians who have practiced about fifty years. They were Drs John J Lindsay, who graduated from the University of Maryland School of Medicine in 1887, James L Jeffenes, from New York University Medical College in 1889, and Louis J Blake, from the University of Pennsylvania School of Medicine in 1888. All live in Spartanburg. Dr Roy P Finney, president of the society, presided at the meeting and the speakers included Drs Daniel L Smith, Spartanburg, James M Northington, Charlotte, N C, and the guests of honor.

TEXAS

North Texas Meeting—The semiannual meeting of the North Texas Medical Association was held in Paris, June 22-23. Dr Howard R Dudgeon, Waco, recent president of the State Medical Association of Texas, was the guest speaker at a banquet, and guests for the scientific sessions were Drs Titus H Harris, Galveston, who spoke on "Vitamin Deficiency as the Etiological Factor in Acute and Subacute Toxic Organic Mental Reactions", Calvin R Hannah, Dallas, "Brain Injuries Occurring at Birth", Karl J Karnaky, Houston, "Diagnosis and Treatment of Trichomonas Vaginitis," and Arthur C Scott Sr, Temple, "Problems in Early Diagnosis of Cancer"

VERMONT

Personal—Dr Lester E Judd, Barre, has joined the staff of the Vermont Tuberculosis Association and will make a study of silicosis.

VIRGINIA

Society News—Drs Edward H Cary, Dallas, Texas and William B Mason Washington, D C, were the guest speakers at the annual meeting of the Virginia Society of Otolaryngology and Ophthalmology at Staunton, May 8. Dr Cary discussed "Affections of the Optic Nerve" and Dr Mason, "The Use of Protosil and Protynin in the Treatment of Acute Streptococcus Infection in the Ear Nose and Throat." Dr Marshall H Hood, Portsmouth, was elected president and Dr Charles T St Clair, Bluefield, W Va, secretary.

WASHINGTON

State Medical Meeting at Seattle—The forty-eighth annual meeting of the Washington State Medical Association will be held in Seattle July 19-22, at the same time as the annual course of graduate lectures presented by the University of Washington. An announcement of the course appeared in THE JOURNAL, June 19, page 2148. Two of the lecturers will address the association meeting Tuesday afternoon. Drs Hans Lisser, San Francisco, on "Recognition and Treatment of Childhood and Adult Myxedema" and Waltman Walters, Rochester, Minn, "Operative Treatment of Lesions of the Suprarenal Gland and Pancreas." In addition, the following Washington physicians will appear on the program Wednesday afternoon.

Dr Siegfried F Herrmann Tacoma Carcinoma of the Pancreas
Dr Henry S Atwood Yakima Spinal Anesthesia with Special Reference to Dosage
Dr Darcy M Dayton Tacoma Progress in Pediatrics
Dr Leslie L Nunn Vancouver Cancer of the Breast in the Young
Dr Alfred O Adams Spokane Technique of Transplanting Full Thickness and Split Thickness Skin Grafts

The annual golf tournament will be held Monday July 19 at the Broadmoor Golf Club, and the annual dinner and dance Wednesday evening at the Olympic Hotel.

WEST VIRGINIA

Personal—Dr Harwood A Taylor, Mullens, has been appointed superintendent of the McKendree Emergency Hospital, McKendree, succeeding Dr John N Reeves, resigned.

State Medical Election—Dr Charles W Waddell, Fairmont, was elected president of the West Virginia Medical Association at the annual meeting in Clarksburg in May. He will take office Jan 1, 1938. Drs Herbert H Haynes, Clarksburg and Arthur A Shawkey, Charleston, were elected vice presidents. The 1938 meeting will be at White Sulphur Springs.

Society News—Dr James R Bloss, Huntington, a member of the Board of Trustees of the American Medical Association, addressed the Ohio County Medical Society, Wheeling, April 2, on "The Indications for Therapeutic Abortion"—Dr Warren T Vaughan, Richmond, Va, addressed the Kanawha Medical Society, Charleston, April 13, on "Management of the Hay Fever Patient"—Dr Henry Klinzing, Pittsburgh, addressed the Parkersburg Academy of Medicine, April 1, on "Medical Aspects and Treatment of Peptic Ulcer"—Dr Harvey G Beck, Baltimore, addressed the Cabell County Medical Society, Huntington, May 13, on "Chronic Carbon Monoxide Poisoning"—At a meeting of the Monongalia County Medical Society, Morgantown May 7, Dr Claude S Beck, Cleveland, gave an address on "Recent Advances in Cardiac Surgery"

WISCONSIN

Personal—The Northwestern University Alumni Association recently presented an award of merit to Dr Stanley J Seeger, chief of staff at the Milwaukee Children's Hospital and the Columbia Hospital "in recognition of worthy achievement which has reflected credit on Northwestern University and her alumni"—Dr Carl J Rollefson, head of the department of physiology at State Teachers' College, Superior, since 1912, has retired.

District Meetings—The Fourth Councilor District of the State Medical Society of Wisconsin held its annual meeting at Lancaster, May 26, with the following speakers. Drs William D Stovall, Madison, on "Biopsy in the Diagnosis of Early Cancer", William S Middleton Madison, "Cardiac Decompression," and George B Eusterman, Rochester, Minn, "Dyspepsia and Hints on Diagnosis and Treatment." Dr Stephen E Gavin, Fond du Lac, president of the state society, discussed organization activities.—At the annual meeting of the Ninth Councilor District in Stevens Point in May, Drs Roscoe L McIntosh and William J Bleckwenn, Madison, discussed "Treatment of Syphilis from a Dermatologic Standpoint" and "Neurosyphilis in General Practice" respectively.

PHILIPPINE ISLANDS

Society News—At a recent meeting of the Manila Medical Society the speakers were Drs Honoria Acosta-Sison, on "The Advantages of the Semilunar Transverse Uterine Incision in Laparotrachelotomy", Regino J Navarro, "Hematology in Filipinos Normal Blood Iron Content" and Narciso Cordero "Present Status of Hemoglobin Estimations"—The Pampanga Medical Society gave a banquet in honor of Dr Juan S Fernando, recently appointed chief health inspector of Central Luzon and the Southern Islands. A committee has been appointed to take charge of funds for the erection of a monument to the late Dr Gregorio Singian.

GENERAL

Bequests and Donations—The following bequests and donations have recently been announced

Lenox Hill Hospital \$5 000 Misericordia New York Foundling St Vincent's Seton and St Francis hospitals and St Joseph's Hospital for Consumptives all of New York \$1 000 by the will of the late Baroness Anna M. von Zedlitz
New York Hospital New York will ultimately receive \$127 736 under the will of Katherine Grace Snyder
St Luke's Hospital New York, \$20 000 from the estate of Mrs. Lillian J. Langford

Society News—Dr. Walter L. Carr, New York, was elected president of the American Association of Medical Milk Commissions at its annual meeting in Atlantic City, June 8, and Dr. Paul B. Cassidy, Philadelphia, was reelected secretary-treasurer.—Mrs. Marjorie B. Illig, lay field representative of the American Society for the Control of Cancer, New York, has been appointed national commander of the Women's Field Army to succeed Mrs. Grace Morrison Poole, who will be honorary national commander.—Dr. Jay Arthur Myers, Minneapolis, was elected president of the American Academy of Tuberculosis Physicians at the annual meeting in Atlantic City in June.—Dr. Ezra R. Bridge, Rochester, N. Y., was elected president of the American Sanatorium Association at the annual convention in Milwaukee May 31.—Dr. William W. Plummer, Buffalo, was chosen president-elect of the American Orthopedic Association at the annual meeting in Omaha June 2-4, and Dr. Frederick C. Kidner, Detroit, was installed as president. Dr. Ralph K. Ghormley, Rochester, Minn., was reelected secretary.—Dr. Arthur W. Elting, Albany, N. Y., was elected president of the American Surgical Association at its annual meeting in New York June 3-5, and Dr. Charles G. Myrter, Boston, reelected secretary.—Dr. Gordon Berry, Worcester, Mass., was elected president of the American Bronchoscopic Society at the annual session in Atlantic City June 2. Dr. Lyman G. Richards, Boston, is secretary.—Dr. James Herbert Mitchell, Chicago, was elected president of the American Dermatological Association at its annual meeting June 4 at Sky Top, Pa.—Dr. Harold I. Lillie, Rochester, Minn., was elected president of the American Laryngological, Rhinological and Otolological Association at the annual meeting in Atlantic City in June and Dr. Samuel J. Kopetzky, New York, was installed as president. Vice presidents elected are Drs. Louis H. Clerf, Philadelphia, Murdock S. Eguen, Atlanta, Ga., James B. Costen, St. Louis, and Arthur C. Jones, Boise, Idaho. Dr. Carlton Stewart Nash, Rochester, N. Y., was reelected secretary.—Dr. Thomas B. Magath, Rochester, Minn., was chosen president-elect of the American Society of Clinical Pathologists at the annual meeting in Philadelphia June 2-3. Dr. Stanley P. Reimann, Philadelphia, received the Ward Burdick award for his research on cancer, Dr. Henry F. Hunt, Danville, Pa., received a gold medal for an exhibit on the etiology of eclampsia and Dr. Bernhard Steinberg, Toledo, a silver medal for an exhibit on the etiology and treatment of acute peritonitis.—Dr. Charles A. Eisberg, New York, was elected president of the American Neurological Association at its annual meeting in Atlantic City in June. Drs. Walter D. Shelden, Rochester, Minn., and Percival Bailey, Chicago, were chosen vice presidents and Dr. Henry Alsop Riley, New York, was reelected secretary.—Dr. Temple S. Fay, Philadelphia, was chosen president of the Harvey Cushing Society at its meeting in Philadelphia, May 6-8, Dr. Frederick L. Reichert, San Francisco, vice president, and Dr. Louise C. Eisenhardt, New Haven, Conn., secretary.

FOREIGN

International Congress on Mental Hygiene—The second International Congress on Mental Hygiene will be held in Paris, July 19-25, with Dr. E. Toulouse, Paris, as president. Among physicians of the United States who will appear on the program are

Dr. Howard C. Taylor, New York, Eugenic Sterilization Laws and Results of Their Application
Dr. Franklin G. Ebaugh, Denver, Progress of Psychiatric Education in the United States and Canada
Dr. Ruth E. Fairbank, Baltimore, Factors Considered to Be Favorable and Unfavorable to Youth
Dr. Gilbert J. Rich, Milwaukee, Recreational Therapy in Preschizophrenic Patients
Dr. Arthur H. Ruggles, Providence, R. I., Mental Hygiene and the Individual
Dr. Samuel H. Epstein, Boston, Psychometric Response of Patients with General Paresis to Treatment
Walter R. Miles, Ph.D., New Haven, Conn., Prophylaxis of Alcoholism
Mr. Clifford W. Beers, New York, secretary of the National Committee for Mental Hygiene, is permanent secretary of the International Committee for Mental Hygiene. The late Dr. William Alanson White, Washington, was president of the international organization.

Government Services

Annual Report of Veterans' Administration

According to the annual report of the Veterans' Administration, there were 120,365 admissions to hospitals during the year ended June 30, 1936, 41,875 remained at the end of the year as compared with 42,984 in 1935, a decrease of 1,109, about 2.9 per cent. A total of 173,817 patients were hospitalized during the year, of whom 168,570 were veterans, representing an increase of 14 per cent over 1935. Of the total remaining in hospitals, 11 per cent were under treatment for tuberculosis, 58 per cent for neuropsychiatric diseases and 31 per cent for general medical and surgical conditions. Of the same group, 38,844 veterans were in facilities controlled by the Veterans' Administration, 1,856 in other government hospitals, and 842 in state or civil institutions. More than 61 per cent were receiving treatment in facilities located in the state of their reported home address.

Deaths in hospitals totaled 8,465, or 6.7 per cent, of the discharges, as compared with 7,253, or 7 per cent, in 1935. Of the total number of deaths 5,193, or 61.35 per cent, occurred among patients under treatment for general conditions, 2,058, or 24.31 per cent, for pulmonary tuberculosis, and 1,214, or 14.34 per cent, for neuropsychiatric diseases. A total of 95,742 World War veterans were discharged after treatment for diseases or conditions not connected with service and 11,107 for disabilities of service origin. Since March 1919, when the government facilities were authorized for treatment of veterans of the World War, there have been 1,568,786 admissions to hospitals. The total admitted in 1936, 120,365, represents an increase of 12.6 per cent over 1935 but is 19 per cent less than the peak of 148,662 in 1932. The administration reported 9,586 veterans under domiciliary care June 30, 1936, as compared with 9,323 the previous year. Of this number 84.21 per cent were veterans of the World War, with an average age of 44, 7,208 were disabled by general medical and surgical conditions, 2,152 by neuropsychiatric diseases and 226 by tuberculosis. About 87 per cent of the admissions were for non-service connected disabilities. Of the 25,488 veterans discharged after an average period of five months' domiciliary care, 21,811 were World War veterans.

At the end of the year covered by the report the administration was operating facilities at eighty locations in forty-three states and the District of Columbia, which provided a total of 45,873 beds, an increase of 1,080 over the number available on June 30, 1935. There were 18,756 beds available for domiciliary care, a decrease of 1,317 from the number on June 30, 1935. The total number of beds available in facilities controlled by the administration was 64,629 as compared with 64,866 in 1935, a decrease of 237.

During the year the net operating expense for all hospital and domiciliary facilities controlled by the administration totaled \$46,860,361.49 of which \$42,386,484.65 was for hospital and \$4,473,876.84 for domiciliary facilities. Throughout the year there was a daily average of 40,972 patients of all types under treatment, and a daily average of 12,008 beneficiaries receiving domiciliary care as compared with 39,030 and 10,406, respectively during the fiscal year 1935. The per diem cost of operation for all hospital facilities was \$2.82, as compared with \$2.78 for 1935. A total of 1,094,109 physical examinations for outpatient purposes were made, an increase of 208,760 over the number in 1935. About \$589,564.326 was expended in the various states and the District of Columbia on veterans and their dependents for both direct and indirect benefits. When completed construction under way at the close of the report will provide about 3,400 additional beds while approved or proposed new construction provides for the erection of new facilities in Detroit, White River Junction, Vt., Reno, Nev., middle Tennessee and Alabama for extensions to existing facilities at twenty-seven locations in twenty-two states, and for the conversion of the facilities at Roseburg, Ore., and Tuscaloosa, Ala., to hospitals of the neuropsychiatric type. A new cancer center was opened in January 1936 at Atlanta, Ga., equipped with high voltage x-ray therapy machines and radium bringing the number of cancer centers of the administration to six, providing a total of 502 beds. Centers for the special surgical treatment of pulmonary tuberculosis were established toward the end of the year at six facilities: Aspinwall, Pa., Castle Point, N. Y., Legion, Texas, Oteen, N. C., San Fernando, Calif., and Tucson, Ariz., and special attention was paid to graduate courses in various subjects, including two classes in allergy at the facility in Aspinwall.

The British Medical Association and the Treatment of Fractures

The report of the Fracture Committee of the British Medical Association shows an enormous annual loss in industry due to accidents resulting in fractures and associated injuries of the limbs. The report recommended the extension of organized clinics for the treatment of fractures because of the much better results achieved in them. Whereas 276 cases treated by unorganized methods involved incapacity for a period of 13,206 weeks, this period could have been reduced to 4,440 weeks if the treatment had been given in organized clinics. Incapacity remained permanent in only 1 per cent of the cases treated in organized clinics, while 37 per cent of the patients otherwise treated remained incapacitated. The committee therefore proposed a scheme for a model fracture unit which would be in charge of a special surgeon and would provide for inpatient treatment and for weekly and biweekly clinics for ambulant cases. It suggested that employers of labor on a big scale might provide their own rehabilitation centers whether attached to hospitals or situated in the factory. In this matter employers, hospitals, physicians and insurance companies should maintain the closest cooperation.

The report of the Fracture Committee aroused much interest both in medical and in nonmedical circles. A number of divisions of the British Medical Association arranged lectures on the subject of fractures, the plans of certain new hospitals have included provision for fracture units, and the General Federation of Trade Unions convened a conference to consider the application to industry of the recommendations of the Fracture Committee. The Home Office and the Ministry of Health have appointed an interdepartmental committee to inquire into the arrangements at present in operation with a view to the restoration of the working capacity of persons injured by accidents and to report on what improvements are desirable, having regard to the report of the British Medical Association.

Sir Arthur Hurst

The conferring of a knighthood, among the coronation honors, on Dr Arthur Hurst, senior physician to Guy's Hospital, is a recognition of the most important researches carried out by any British physician of the present generation. Educated at Magdalen College, Oxford, and Guy's Hospital, after a distinguished career as a student, he became Radcliffe traveling fellow in 1905 and studied in Munich, Paris and America before he became assistant physician in 1907. He took over the neurologic department and his work on war neuroses was so important that he represented the war office at the congress of the American Neurological Society. In 1918 he became full physician to Guy's Hospital and in addition to editing its reports has been responsible for an enormous amount of original work. It is interesting to survey the landmarks of modern medicine to his credit. 1 The earliest radiologic investigations on deglutition, intestinal movements and defecation in man, with subsequent application to the study of constipation and its classification into colonic constipation and dyschesia. 2 The sensibility of the alimentary tract in health and disease. 3 War neuroses, especially proof of the hysterical nature of contractures following wounds and their cure by psychotherapy. The psychology of the special senses and their functional disorders and a lecture to the neurologic section of the American Medical Association in 1919. 4 The functional element in organic diseases of the nervous system and rheumatism, and the hysterical nature of the so called pernicious vomiting of

pregnancy. 5 The physiology and pathology of the sphincters achalasia of the cardia the cause of megaloesophagus, and of the sphincter, the cause of Hirschsprung's disease. 6 The constitutional factor in disease with the revival of the old conception of diathesis. 7 The proof that subacute combined degeneration of the cord is associated with achlorhydria and is a result of the same underlying causes as pernicious anemia. 8 The control of the status asthmaticus by the continued administration of epinephrine. 9 The unity of gastric disorders (Alvarez lectures to the American Gastro-Enterological Association in 1933). 10 The proof that "intestinal auto-intoxication" is not due to constipation but to the injudicious use of aperients and enemas.

This teaching is to be found in addresses and papers published in medical journals and also in his books "Constipation and Allied Intestinal Disorders," "Gastric and Duodenal Ulcers," "War Neuroses," "Psychology of the Special Senses and Their Functional Disorders" and "Essays and Addresses on Digestive and Nervous Diseases and on Addison's Anemia and Asthma."

A Bill to Prohibit Illegal Practice

A bill to modify a law passed in 1892 aiming to close the loopholes in that law was presented by Dr Cousin at the Jan 19, 1937, session of the lower house (chambre des deputes) of the legislature. The bill prohibits any one who is not licensed to take any part in the treatment of a patient. Thus, making a diagnosis cannot be strictly considered as illegal practice. Reference was made in a recent letter to the increase of those quacks who make a diagnosis by exerting pressure on the sympathetic nerve endings in the nasal septum, the "sympathotherapists," and a still later form of quackery, "radiesthesia," in which a diagnosis is made according to the oscillations of a pendulum held in front of the photograph of a patient. The advertisements of the miraculous cures effected by these two newer types of quackery fill column after column in many daily journals here. So far these quacks have escaped the illegal practice clauses of the existing law, because if called on to treat a patient they employ, as an assistant, some licensed physician, who in the present medical crisis in France can be readily found to be willing to receive money in this unethical manner. Although any one is prohibited from "treating" patients in the strict interpretation of the term, there is no clause in the present law which prevents any one from giving 'care' to persons in good health. Hence all sorts of vaccine cures, electric treatments, and the like which can be followed by serious consequences, are still considered as "within the law."

The simple infliction of a fine on a quack is not considered by him as anything more than an ordinary "overhead" expense and does not prevent him from continuing to carry on with his methods. According to an article by Jean Mignon in the April 4 *Concours medical* the present law ought to be modified as follows:

1 The definition "illegal practice of medicine" should include the act of participation, even in the presence of a licensed physician, in the making of a diagnosis or treatment of a patient by verbal or written methods, by circulars or other means of publicity. The term treatment should include any act which has either a hygienic or an anesthetic objective necessitating the utilization of minor surgical procedures or electrotherapy.

2 Only medical students or the assistants of a licensed practitioner can take part in the treatment of a patient, and then only under his or her supervision and responsibility.

3 The penalty for a first offense ought to be raised to from 500 to 1000 francs and fifteen days imprisonment, and for a

second one to from 1,000 to 5,000 francs and imprisonment for from one to three months, with confiscation of all apparatus

4 Any foreigner licensed to practice in France or its colonies must state the name of the university from which his or her diploma was received, after the term "doctor"

Mineral Waters and Bacillus Coli Content

Every mineral water, before being allowed to be sold in France, must be examined by the laboratory of the public health ministry. As the presence of *Bacillus coli* is considered the best evidence of water pollution, the results obtained at this laboratory were reported at the April 20 meeting of the Academie de medecine by Cruveilhier and Magnier de la Source. They confirmed previous studies as to the upper (1185) and lower (385) limits of hydrogen ion concentration at which *B. coli* is no longer viable. Such limits are never found in mineral waters and hence their hydrogen ion concentration does not prevent the development of *B. coli*. On the other hand, it does not interfere with identification of the various strains of this organism, because they retain their indole producing property as long as they are viable.

Mineral waters can be divided into three groups according to whether or not they favor the conservation and development of *B. coli*. Certain waters, such as those rich in sodium chloride, calcium and sodium carbonate, or sodium sulfate, are a poor medium for *Bacillus coli*. Others, at least over a period of several months, do not have much influence on its biochemical properties. In this group belong waters containing magnesium carbonate, small amounts of sodium bicarbonate or arsenic, and those rich in albumin. Others, finally, although they do not favor growth of the bacterium, permit it to live for some time, practically uninfluenced. In this group can be placed waters with slight mineral content. None of the mineral waters that were studied were mediums unfavorable to the existence of *B. coli*.

Foch Foundation Changes Name

A very large hospital in one of the suburbs (Suresnes) of Paris is nearing completion. It, like the recently constructed Beaujon Hospital in another suburb (Clichy) of Paris, is eleven stories in height, thus surpassing in this respect any other European hospital. The Suresnes hospital had been called "The Foch Foundation," but in order to avoid confusion it has been decided to change the name to "Medical Foundation of Mount Valerian," because a hospital in Paris which provides care for wounded veterans is termed "Foch Hospital." The honorary president of the almost completed Medical Foundation of Mount Valerian is the widow of Marshal Foch, but the president of the ladies auxiliary, which deserves credit for the major portion of the work of building this new hospital, is Mrs. Jacques Balsan (nee Vanderbilt).

The Suresnes institution is located in a densely populated suburb, and one of its chief objectives is to provide hospital facilities for members of the liberal professions and middle class wage-earners whose means do not permit the expense of care in private hospitals. The new hospital is only fifteen minutes by automobile from the center of Paris.

Method of Conservation of Blood Specimens

Every candidate in France for the medical degree must present a thesis based on clinical problems. As a subject for his graduating thesis, Ducros-Gastinel studied the various methods hitherto employed in preventing changes in blood taken for the Bordet-Wassermann reaction. He states that it often occurs that the blood is so altered when it reaches the laboratory as to make the utilization of it impossible. He attempted to find a method which, while preventing bacterial contamination, would not interfere with the specific properties utilized in carrying out the Bordet-Wassermann reaction. It was found that all reagents hitherto used to eliminate contamination alter or modify one or several factors which enter into the reaction,

hence all, after having been given a trial, were discarded. Only the derivatives of quinoline proved to be efficacious. The neutral sulfate of oxyquinoline has strong antiseptic properties and is only slightly toxic and caustic in solution. The author found that this antiseptic had no influence on coagulation, retraction of the clot and exudation of serums taking place in a normal manner. The solution added to blood serum in a proportion varying from 1:100 to 1:600 causes flocculation of the serum. When a 1:1,000 solution is added, the serum remains clear. The use of the neutral sulfate of oxyquinoline does not confer any hemolytic activity to the lipid solution used as an antigen, does not interfere with sensibilization of the red cells and does not prevent or diminish the atoxic property. The concentrations employed were 1:5,000, 1:10,000 and 1:20,000. Forty blood specimens, of which twenty showed a distinctly positive reaction in all degrees, four a feebly positive reaction and sixteen a negative reaction, were submitted to comparative tests for both heated and nonactivated serums. There was not the slightest difference noted in this double control. The antiseptic power of the neutral sulfate of oxyquinoline solution was marked in 1:5,000 and even in 1:10,000 dilution. The blood remained unaltered long enough to permit the serologic examination to be made under favorable conditions. In spite of the proved value of this method, the necessity of taking the blood under aseptic conditions should not be changed.

Tuberculin Reactions in Nurses

In 1935 Troisier, Bariety and Nico reported observations of the relative frequency, especially among recruits from rural districts, of negative epidermal reactions in the French army. They found 25 per cent frankly negative, 60.6 per cent distinctly positive and 14.4 per cent of reactions that were doubtful but tended toward the positive side. In a second paper read by these authors at the April 6 meeting of the Academie de medecine they presented the results of 100 observations on nurses between 19 and 30 years of age in the new Beaujon Hospital. Both the epidermal and dermal reactions were employed. In a first group of sixty nurses between 19 and 23 years of age they found 63.3 per cent positive and 36.7 per cent negative epidermal reactions. Of the latter group the dermal reaction was positive in 28.5 per cent and negative in 82 per cent. In a second group of forty nurses from 23 to 30 years of age the epidermal reaction was positive in 72.5 per cent and negative in 27.5 per cent. Of the latter, the dermal reaction was positive in 12.5 per cent and negative in 15 per cent.

The chief interest of this study is to show that, even in a large collectivity like Paris, among adolescents and young adults the index of tuberculinization is not what it is generally considered to be. Twenty-eight and five-tenths per cent of the nurses up to the age of 23, one out of six or seven (15 per cent) up to the age of 30, react to tuberculin in the form of the dermal reaction like young immune children, raised in healthy surroundings. This study shows the great value of the tuberculin reaction as a clinical test, even for young adults.

Exemption of Professors from Compulsory Retirement Law

Some time ago a law was passed according to which all members of medical faculties who had reached the age of 65 and whose rank was that of professor must retire from the position of attending physician, surgeon and the like in public hospitals and cease their work as teachers in the medical schools of France or its colonies. This law, if enforced strictly, would have affected many of the present-day outstanding medical men.

Fortunately, a government ruling of Dec. 31, 1936, has created a special class for those holding the rank of professor in the medical schools but the number who could be included in this exemption was limited to thirty. The list of those who will be able to continue their teaching work to the age of 70

includes Professors Gosset, Ombredanne, Bezançon, Carnot, Claude and Tiffenau of Paris, Professor Berard of Lyons and Professor Boin of Strasbourg

It is of interest to note in this connection that the Rumanian parliament has just passed a bill according to which Professor Marinesco of Bucharest, the internationally known neurologist, can continue his teaching activities without any age limit. Reference was made in a previous letter to a proposed law here which would compel the members of all the liberal professions to surrender their diplomas at the age of 65. There have been so many protests to such a law that the bill has made but little progress.

International Medical Days During the Paris Exposition

The program has just been published of a series of conferences on endocrine problems to be held in Paris from June 26 to 30 inclusive. Many clinicians and research workers from most of the European countries will take part in the discussions. The first day will be devoted to general introductory papers, such as (1) neurohormonic and hormonal control, by Professor Roussy (Paris), (2) hormonal control as related to internal medicine, by Professor Mauriac (Bordeaux), and (3) hormonal control as related to surgical problems by Professor Leriche (Strasbourg). The mornings of the other days will be devoted to visits to Paris clinics and the afternoons to papers on the endocrine influence on the function of various organs and tissues.

Award of Prize by Academy of Medicine

At a recent meeting of the Academy of Medicine in Paris the Prince Albert of Monaco prize amounting to 100,000 francs (nearly \$5,000) was awarded to Professors Boin and Ancel of the Strasbourg Medical School for their research work on sex hormones.

MOSCOW

(From Our Regular Correspondent)

June 1, 1937

Degrees for Scientists

Degrees for scientists and university teachers are established by the Council of People's Commissars of the Union of Socialist Soviet Republics in a decision issued March 20. There are to be two science degrees, that of a Candidate of Science (approximating the Master of Science degree in English-speaking countries) and that of a Doctor, and three degrees for university and research workers: assistants (equivalent to instructors in American universities), docents (equivalent to assistant professors) and professors. Aspirants to the degree of Candidate of Science must pass certain examinations and publicly defend a dissertation on any chosen subject. Doctors' degrees are granted to candidates of science who publicly defend a dissertation for a doctor's degree in any chosen subject. Persons already known by their scientific works, discoveries or inventions, and persons having the title of professor, may be allowed to defend a doctor's dissertation without possessing the degree of candidate of science. Prominent scientists, explorers and inventors, may be granted a doctor's degree without defending dissertations. Science degrees will be granted in eighteen different branches of science, including medicine, pharmacy, veterinary science, biology, chemistry, physics and mathematics. The title of instructor (assistant) will be given to university teachers or to research workers working under the supervision of a docent or professor. The title of docent will be given to candidates of science who teach or conduct research in universities and research institutes under the supervision of a professor. The title of professor will be given to persons possessing the degree of a doctor who teach or conduct research in universities and research institutes.

Appended to the decree are two lists of universities and research institutes which are entitled to grant degrees of doc-

tors and candidates of science. The first list contains sixty-eight universities and institutes controlled by various people's commissariats in the different republics. The second list contains thirty-one names of universities and institutes. The People's Commissariat of Health establishments that have the right to grant degrees of doctor and candidate of science are the All-Union Institute of Experimental Medicine, the First and Second Moscow and First and Second Leningrad medical institutes, the medical institutes of Kiev, Charkov and Kazan, the Leningrad pedagogic institute and the Moscow and Leningrad Institute for physicians as well as the Leningrad Military Medical Academy. The following establishments have received the right to grant only the degree of candidate of science: the medical institutes of Tomsk, Rostov-on-the-Don, Saratov, Voronezh, Odessa, Minsk, Tashkent, Baku and Tiflis, as well as the Kharkov and Leningrad pharmaceutical institutes. All other institutes that formerly had the right to grant scientific degrees can do so only until May 20, after this term any dissertation defense in the institutes not mentioned will be forbidden. The degrees must be confirmed by the Highest Attestation Commission of the All-Union Committee on Higher Schools.

The All Union Antimalaria Conference

An all union conference on the campaign against malaria was held in Moscow, April 25-30. It was attended by heads of the union republics, representatives of large antimalaria organizations and directors of tropical institutes. A report entitled "Results of Combating Malaria in 1936 and the Plan of Work for 1937" was made by Dr. Buslayeva, acting chief of the malaria department of the Peoples Commissariat of Health of the Union of Socialist Soviet Republics. Thirty-two million inhabitants were examined last year for malaria, while more than five million were treated for malaria. More than 2,866,000 hectares of land infected with malaria mosquitoes were sprayed by airplanes, while land spraying and petroleum treatment were applied on 239,000 hectares. It involved an expenditure of about 30 million rubles. The number of malaria cases in 1936 fell by 26.6 per cent as compared with 1935.

The plan for the current year comprises government appropriations of 129.4 million rubles for combating malaria. Training of malaria specialists has been extended. Last year 1,082 physicians and 1,032 assistant physicians were trained at special two months courses in addition to other workers engaged in the struggle against malaria. About 68,000 collective farmers are being trained to assist physicians in carrying out these measures. A synthetic quinine substitute of Soviet manufacture is the chief drug used for malaria treatment and it gives excellent results.

In the resolution passed at last year's conference an obligation was undertaken to lower the incidence of malaria in 1936 by an average of 30 per cent throughout the Union. This decision was carried out. According to the resolution made by the conference this year, malaria, which is highly prevalent in certain regions, should disappear in the Soviet Union by the end of the third five year plan, as a result of treatment and preventive measures carried out on a large scale. Various organizations engaged in combating malaria will have many more malaria specialists. In order to popularize methods for combating malaria, special cinema films will be made. The conference decided to obtain government approval for calling an all union malaria congress at the beginning of next year.

The French Soviet Conference

A group of French scientists visited the Soviet Union from March 25 to April 7. The delegation participated in the Franco-Soviet conference on surgery and microbiology. The French delegates included Prof. Alexandre Besredka of the Pasteur Institute, Prof. Marcel Lisbonne of the Montpellier Faculty of Medicine, Dr. Henri Rouvillois, sanitary medical inspector of

the French army, Drs Paul Giroud and Eugene Wollman, both of the Pasteur Institute laboratory, Professor Macheboeuf of Lille, Prof Pierre Fredet, Firmin Cadenat, Robert Monod, Ernest Desmarest, Robert Merle d'Aubigne and Colonel Marcel Liegeois of the French military hospitals. On their arrival in Moscow the guests were greeted by G. N. Kaminsky. The French scientists visited the All-Union Institute of Experimental Medicine. The head of the laboratory, Professor Ermoljeva, acquainted them with the action of lysozyme, a substance capable of destroying certain microbes by inhibiting their growth. Lysozyme, obtained from egg white, cabbage and horseradish, kills the diphtheria and typhoid bacilli. The delegation also visited Moscow and Leningrad medical establishments.

March 27-30 a joint Franco-Soviet scientific conference was held at which surgical and microbiologic problems were discussed. Dr Liegeois described methods of inoculation against diphtheria, tetanus and typhus applied in the French army. In the inoculation of 70,000 persons there were no complications. Two inoculations are enough, instead of three used in other methods. Speaking about typhus immunization, Dr Giroud pointed out that best results were given by vaccination with an emulsion of desiccated brains of rats infected with typhus. He explained that the vaccine was prepared from living virus by Charles Nicoles and Legret. The mass vaccination made in Morocco by the Casablanca branch of the Paris Pasteur Institute has given brilliant results since 1934. For this purpose the mice typhus virus in lice was used. It stopped the exanthematic typhus epidemic twenty-six days after the beginning of the vaccination.

March 29, in the Neurosurgical Institute, local anesthesia was discussed. April 1 a public session of the conference was held with more than 2,000 Moscow physicians in attendance. Prof Alexandre Besredka delivered in Russian a report on vaccination against cancer, Professor Monod spoke on general noninhalation anesthetics used in French surgical practice.

The Moscow Institute of Physiology

The Institute of Physiology was founded in 1929 in Moscow by the physiologist Prof Lina S. Stern, well known for her work on oxidation processes in living tissues. The principal questions investigated by the institute are at present problems of barrier function in the living organism, problems of sleep and oxidation processes. The researches of the institute have been reported at many conferences and congresses, including the fourteenth and fifteenth international congresses of physiology. They are published in the three symposiums of transactions and in a volume devoted to the thirty years' work of Lina S. Stern. Since 1936 a monthly bulletin of experimental biology and medicine in Russian, English, French and German has been published by the institute, in which preliminary reports of experimental work made in different Soviet institutes are printed, acquainting readers with the achievements in experimental biology and medicine.

The Campaign Against Cancer

The Central Oncologic Scientific Institute of the People's Commissariat of Health in Moscow is the leading organization engaged in the study of tumors. The institute has a surgical clinic with ninety beds under the direction of Prof Jacob M. Brouskin, an x-ray and radiologic department, an experimental laboratory, a department of morbid anatomy, biomorphologic, microbiologic, biochemical and biophysiology laboratories, a laboratory of genetics, and departments of social oncology, statistics and other subjects. The oncologic institute has branches in Rostov-on-the-Don, Sverdlovsk, Voronezh and Novosibirsk. In Moscow there are twenty-two oncologic "points" in large ambulances where oncologists examine patients

and direct those with tumors for ambulatory and hospital treatment to the central institute. In 1935 the institute organized five months' graduate courses for surgeons, gynecologists and radiologists working in other districts. They receive a theoretical and practical course of tumor study—morbid anatomy, pathologic morphology, experimental oncology, immunology, cytology, genetics, operative surgery in the surgical and gynecologic clinic of malignant growth, and oncologic statistics. Having attended this course of lectures, the physicians, after graduating, become organizers of branches of the institute in the provinces. The institute does educational work also. Its scientific collaborators and qualified specialists deliver lectures to physicians, hospital workers and the general population on different questions of prophylactics and the treatment of tumors.

The Leningrad Cancer Institute

At the March 23-29 sessions of the Leningrad Institute of Roentgenology, Radiology and Cancer, summing up the institute's work for the past year, attention was centered chiefly on the effect of x-rays on the nervous system. Of greatest interest were the institute's observations proving that this effect is due not to the direct action on the affected organ but to the influence on the sympathetic nervous centers. It confirms Prof M. S. Nemenov's theory regarding the biologic action of x-rays and makes desirable changes in current methods of treatment. A new method for treating stomach ulcers by x-rays was described, consisting of the treatment of the spinal cord centers directing the stomach functions. Forty-four papers were read and about 200 scientists of Leningrad, Moscow, Kiev, Minsk and other cities of the Soviet Union took part in the sessions.

Increase in Birth Rate

In January 1937, compared with the same month of last year, the birth rate increased 21.6 per cent. The highest birth rate is recorded by the Ukrainian republic, an increase of about 70 per cent. In the capital cities of the Soviet republics the increase was also very high during the first three months of this year. By decree of June 27, 1936, 566 million rubles is to be paid this year by the government to assist mothers with large families. Incomplete data of the People's Commissariat of Health show that 270,000 mothers are receiving government help.

National Health Insurance

Nearly two years ago the union government appointed a commission to inquire, for the third time, into the desirability of establishing a system of national health and invalidity insurance. Two previous commissions had reported in its favor, but the government has been so busy with party politics that social legislation has had little chance of being attended to. The medical profession has repeatedly declared itself in favor of some state aided contributory scheme of national invalidity insurance and the present commission, which has just published its lengthy report, has accepted virtually all the recommendations made by the Medical Association of South Africa, which spoke as the mouthpiece of the profession. The commission recommends that the scheme shall apply, for the present at least, only to urban areas, it is manifestly impossible, under present circumstances, to apply it to the sparsely populated rural areas. Every employed person earning less than £400 a year in wages or salary is to fall under it, and the contributions to be exacted from the employer, the workman and the government respectively are calculated on a liberal scale which makes provision for sick pay, maternity and funeral benefit and full sick benefit, both for the insured and for his

dependents, inclusive of specialist and hospital benefits. The medical profession has asked for a capitation fee of 9 shillings per insured for all those below the £180 yearly income limit and for 13 shillings per caput for all those over that limit. This capitation fee has been fixed after a great deal of discussion and is an attempt at a compromise between the higher fees now paid by the rich benefit societies on the Rand and the poorer medical benefit societies in the coastal areas. The commission recommends that it be accepted and that contracts be entered into with the medical association for medical service under the act when it becomes law. Unfortunately there is no immediate prospect of an invalidity insurance act appearing on the statute book. This year's legislative program includes only one measure that is of interest to medicine, and that is the proprietary medicines bill, which is an attempt that will certainly be contested by the vested interests involved, to restrict the irresponsible activities of proprietary medicine concerns in advertising their wares in a manner calculated to mislead the public. The bill makes provision for the suppression of trade advertisements that contain statements which cannot be proved, and for the prohibition of the advertisement of anything that claims to be a cure for an incurable disease. A list of what is generally regarded as incurable diseases is given in the schedule and agrees, on the whole, with what would generally be regarded as such by modern science.

Nutrition and Wine Drinking

The Cape is a wine producing country. Indeed, the wine farmer is the only farmer that has so far not come whining to the government for relief and for bounties and protection. Notwithstanding this he is probably more heavily burdened by legislative restrictions on his industry than any other producer in the country. The government has now appointed a special interdepartmental committee to undertake a preliminary survey of the nutritional needs of the country. Incidentally it may be mentioned that there is as yet no fixed standard of nutrition which can be applied to the Negro and native population, and that the assessment of nutrition, by the scientific standards laid down by Franzen in America, appear to be totally unknown here. The nutritional value of sound grape wine, especially as a factor in maintaining the acid-base equilibrium of the blood, has now been established by numerous experiments and wine growers have been urged to carry this dietetic research further by investigating the influence of the "tot system," whereby laborers in the vineyards are given a daily ration of wine, on the physique and working capacity of the Negro and native laborers. Such an inquiry may obtain results that are of real importance in the study of dietetics and the wine industry can well finance it, and indeed carry it out for the KWV, the large Wine Growers Cooperative Society, has not only most complete chemical and bacteriologic laboratories but a staff of well trained research students, who have already done excellent work in investigating and elucidating purely oenological problems.

The Gold Medal for Distinguished Service

The South Africa Medical Association awards, at rare intervals, a gold medal for distinguished services rendered to the profession in South Africa. This year the medal has been unanimously awarded to one who is probably the best known and most respected of all our confreres, Dr W. T. Davies, who for many years has been president of the South Africa Medical Council. Dr Davies, who is also a colonel in the British army, has had a distinguished record of military service and has sat in parliament as a staunch supporter of the late General Botha's policy. He has a high reputation as an able surgeon. He has consistently upheld the high ethical standards of the profession. He is at present on a visit to Europe and has retired from practice.

Deaths

The profession has lost a distinguished and able member in Dr D. J. Wood, who enjoyed somewhat of an international reputation as an ophthalmic surgeon. He had been invited to deliver the Doyne lecture at Oxford this year. For more than thirty years he had served on the medical council and for more than forty-five he had been the chief consulting ophthalmologist in South Africa. He was a man of wide culture, a keen scientist and an indefatigable worker. Up to a day or two before his death he was actively at work and he wrote the last review of a textbook of ophthalmology a few hours before he died. His death was caused by heart failure. Another senior member of the profession who died recently was Dr Hoole, the oldest man on our register, who had retired from practice several years ago. He practiced in the Free State and Cape Colony and was much interested in military medicine and was an enthusiastic volunteer. He had been elected an honorary life member of the association shortly before his death. Dr Bampfylde Daniell, whose death was also recently announced, was another senior member of the association, who had represented it on several occasions at congresses overseas. He was a specialist in anesthesia.

Regulation of the Title X-Ray Specialist

The position of the X-ray specialists has undergone an unfavorable change in recent years. The number of X-ray installations is growing by leaps and bounds, owing to the fact that the peasants falsely believe that only physicians who own an X-ray apparatus can establish a good diagnosis. General practitioners, almost without exception, own X-ray sets, even in villages where there is no electricity and where they have to work their sets with gasoline motors. This situation affects badly the X-ray specialist, who receives his patients from the general practitioners. Another drawback for the X-ray specialist is that the general practitioner shows on his name plate that he possesses an X-ray apparatus, so when a patient drops in, seeing the name plate, for a roentgenogram of a dislocated wrist, he does not refer the patient to the X-ray specialist but keeps the case for himself. The X-ray specialists held a conference to find a remedy for this situation. The result was that the Supreme Health Council made the following resolutions:

- 1 Physicians who have an X-ray apparatus in their office with the aim to establish diagnoses and control the progress of certain diseases on their own patients must not call themselves specialists in radiology and they are not entitled to display on their name plates and on their prescriptions that they have an X-ray apparatus or that they deal with radiologic treatment, and they are not entitled to issue X-ray reports.
- 2 Only such physicians can be acknowledged as X-ray specialists as those who have gained their diploma in Rumanian universities and received a license to call themselves "specialist in radiology."
- 3 Physicians who in 1930 had been in roentgenologic practice for five years receive the title of specialist simply on the verification of the city medical officer of health.

A Novel Method for Establishing the Income of Physicians

The regular method of assessment of the income tax for physicians is as follows. Every physician makes a written declaration in January, in which he declares his taxable income during the preceding year and he compiles the list of his professional expenses. Thereupon he is invited to the financial administration, where a committee consisting of two government officials and a delegate of the local medical chamber makes

the assessment on the ground of the information procured. In general, in their estimation they take as a basis the rent paid by the physician, which is not quite a reliable basis, for even physicians with large incomes may economize and live in a flat of two or three rooms, while one with less income, who obtained a house of six or seven rooms as a dowry with his wife, may live on a large estate. The officials were not contented this year with the rent as a basis, but searched for another one, which in their opinion is more reliable. As druggists are obliged to conduct a ledger on all prescriptions registering the names of the prescribers, government agents visited the drug stores and recorded the number of prescriptions each physician wrote. This of course is not an absolute indication of one's practice but it is something that approaches reality. The greatest losers in this method are the pharmacists, for many of the medical practitioners will stop writing prescriptions when they find that a household remedy or some proprietary medicine will do.

Personal

Dr. Dimitrie Paulian, professor of neurology at the University of Bucharest, has been appointed by the Rumanian Academy of Sciences as a regular member. Professor Paulian is one of the most prominent members of the Bucharest University, whose reputation extends far beyond the boundaries of Rumania. Recently he read a paper at the Vienna Medical Society and some days ago described his own researches in the domain of neurology at some clinics in Paris.

ITALY

(From Our Regular Correspondent)

May 30, 1937

Acclimatization to Tropical Countries

Dr. Amedeo Herlitzka, professor of physiology at Turin University, in a recent lecture before the Accademia dei Lincei of Rome, spoke on acclimatization of Italians in Africa. The problem concerns Italians and, later on, their offspring. The speaker indicated the advisability of establishing two institutions for physiologic studies on acclimatization, one at Addis Ababa and the other at Mogadiscio. The climate of eastern Africa is different in various regions. There is a tropical climate at the seashores and a subtropical climate in the central regions of the country. In certain regions the lowlands have a climate like that of the desert. In the plateaus the climate is temperate but there is the superimposed factor of barometric depression. The main factor concerned with the ability to live in tropical countries is the regulation of temperature. It depends on the bodily perspiration and its evaporation. Excessive perspiration may induce demineralization of the body fluids. Persons living in Africa have to wear light clothing to permit ventilation of the skin. They must also maintain the physicochemical equilibrium of the blood. Feeding will be based on taking carbohydrates, but not to the complete elimination of nitrogen from the food. Alcohol should be prohibited. The speaker said that, in selecting groups for the different climates, only persons with good physical and psychic development can live in the lowlands with a tropical climate.

Tumoral Action of Hydrocarbons

Professor Bisceglie, in a lecture before the Societa Medica di Catania, reported results of experiments aimed at determining the properties of polycyclic hydrocarbons. He found that the injection of 0.02 Gm. of 1,2-antipyrine benzoate, dissolved in olive oil, causes sarcoma of rapid development with infiltration in 100 per cent of the injected rats. Frequently the tumors produce metastases. They "take" by transplantation up to the fourth transplantation. If a smaller dose (0.01 Gm.) of 1,2-antipyrine benzoate solution is injected the proportion of developed sarcoma is from 80 to 85 per cent of the cases with

a longer period of latency for the development of the tumor than that observed in rats which are injected with 0.02 Gm. of the 1,2-solution of antipyrine benzoate. The injection of olive oil without hydrocarbons fails to produce tumor. Professor Bisceglie made a microscopic study of the organs of the animals in the experiment. He found myeloid and paramyeloid degeneration of the liver and the spleen and great increase of megakaryocytes in the spleen. The myeloid degeneration may be substituted in some cases by an activation of the reticulo-endothelial cells, which diffuses itself to the histiocytes of the lung. The renal parenchyma shows amyloid degeneration. The thyroids show signs of hypofunction. All the changes show more clearly when the action of benzene is combined with that of antipyrine benzoate.

Influence of Sun on Sympathetic System

Professor Pende of the University of Rome, in a paper recently read before the Centro Universitario di Nizza, spoke on the mechanism of sudden death and on the influence of sun irradiations on the sympathetic nervous system. Persons who have a sympathetic system in constant condition of hyperstimulation are in danger of sudden death from the effects of intense atmospheric changes and of cosmic and sun irradiations. The speaker's preventive treatment consists in maintaining a low tonus of the vagal nerve by the systematic administration of atropine preparations, in association with certain doses of quinine and camphor.

Personals

Vincenzo M. Palmieri, professor of legal medicine at the Sassari University since 1935, was recently appointed director of the Istituto di medicina legale e delle assicurazioni of the Bari University. Professor Palmieri was born in 1900. He has written about sixty articles on forensic medicine, hematology, industrial diseases and social insurance. His studies on blood groups and biologic diagnosis of drunkenness are regarded as of great value. Recently he published three volumes on blood groups, medicolegal problems of alcoholism and the diminished birth rate.

Deaths

Prof. Angelo Ceconi, emeritus professor of medical special pathology at the Turin University, is dead. He wrote about 190 scientific articles and several books, among which there are a six-volume textbook on internal medicine, a textbook on diseases of the metabolism, a course of clinical lectures and a volume on arthritis and rheumatism. Professor Ceconi was a teacher for thirty years. He wrote in several medical journals and was the associate director of *Minerva medica*.

Marriages

JAMES BEEBE HAWES, Charleston, W. Va., to Miss Helen Forbes White of Greenville, N. C., April 28.

WILLIAM BLOUNT NORMENT to Miss Katherine Williams, both of Greensboro, N. C., in April.

HUGH K. MILLER, Brooklyn, to Mrs. Sarah Frances Barrows Bubendey of New York, May 15.

MYRON J. TREMAINE, Youngstown, N. Y., to Mrs. Esther Wirtz Smith of Chicago, May 5.

CHARLES E. GILL, Boston, to Miss Freda Gertrude Fasenbaker of Baltimore, June 19.

ALBERT G. LOVE, Washington, D. C., to Miss Evelyn Ramsey of Memphis, Tenn., May 4.

JAMES MADISON BATCHELOR, New Orleans, to Mrs. Bernice Bowling Fassman, May 1.

GEORGE W. HOBSON, Pittsburgh, to Miss Florence Klein of Lakewood, Ohio, June 19.

PAUL B. NUTTER to Miss Lois Braden, both of Spokane, Wash., May 17.

Deaths

Lewis Edwards * Kingston, Pa., Jefferson Medical College of Philadelphia, 1891, past president of the Luzerne County Medical Society, president of the board of county commissioners, formerly president of a bank in Edwardsville, member of the board of health, and for several terms school director, county treasurer from 1906 to 1909, for many years a member of the consulting staff of the Nesbitt Memorial Hospital, Kingston, and on the staff of the Wilkes-Barre (Pa.) General Hospital, aged 68, died, April 4, of congestive heart disease and mitral stenosis

Ernest Albert Farrington, Haddonfield, N. J., Dunham Medical College, Chicago, 1902, Hahnemann Medical College and Hospital of Philadelphia, 1909, member of the American Psychiatric Association and the American Association for the Study of Internal Secretions, fellow of the American Association for the Advancement of Science, lecturer in chemistry, Hering Medical College, Chicago, 1901-1904, and assistant professor of chemistry and toxicology, 1904-1905, lecturer in physiology, Hahnemann Medical College of Philadelphia, 1905-1909, medical superintendent of the Bancroft School, aged 56, died suddenly, April 5, of cerebral hemorrhage

Robert Emmett Flannery * Chicago, College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1906, associate clinical professor of surgery, Loyola University School of Medicine, fellow of the American College of Surgeons, served during the World War attending surgeon, Alexian Brothers and St. Mary of Nazareth hospitals, consulting surgeon to St. Anthony's Hospital, aged 53, died, April 20, of peptic ulcer and gastric hemorrhage

Rufus James Coultas * Mattoon, Ill., Bellevue Hospital Medical College, New York, 1890, member of the House of Delegates of the American Medical Association, 1912-1913, 1918-1920, past president of the Coles-Cumberland County Medical Society, formerly member of the school board and board of health, aged 71, on the staff of the Memorial Hospital, where he died, April 27, of heart disease

W. Lee Dodge, Afton, N. Y., University of Buffalo School of Medicine, 1897, member of the Medical Society of the State of New York, past president of the Chenango County Medical Society, served as health officer for the town and village for many years and was a member of the school board, serving as its president for several terms, aged 64, died, April 3, of coronary occlusion

Robert Edward Davison * Pittsburgh University of Pennsylvania Department of Medicine, Philadelphia, 1899, member of the Associated Anesthetists of the United States and Canada and the American Urological Association, served during the World War, on the staff of the Suburban General Hospital, Bellevue, aged 66, died, April 18, of cerebral hemorrhage, while playing golf

Paul Newkirk Bowman * Lieut.-Colonel, M. C., U. S. Army, Denver, University of Pennsylvania School of Medicine, Philadelphia, 1913, served during the World War, entered the medical corps of the U. S. Army as a captain in 1920, fellow of the American College of Surgeons, aged 51, stationed at the Fitzsimons General Hospital, where he died, April 18, of coronary occlusion

Ernest Fahnestock * New York, Columbia University College of Physicians and Surgeons, New York, 1900, fellow of the American College of Surgeons, an honorary police surgeon, visiting surgeon to the New York Foundling Hospital, consulting surgeon to St. Vincent's and Misericordia hospitals, aged 60, was found dead, April 5, of a self-inflicted bullet wound

Walter Henry Chapin, Springfield, Mass., College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1883, member of the Massachusetts Medical Society, formerly medical examiner for city public schools, and city physician, on the staff of the Springfield Hospital, aged 78, died, April 2, of carcinoma of the pancreas

William Howe Doolittle, Lockwood, N. Y., New York University Medical College, New York, 1898, member of the Medical Society of the State of New York, formerly health officer of the town of Chemung, on the staff of the Tioga County General Hospital, Waverly, aged 61, died, April 14, of cerebral hemorrhage and arteriosclerosis

Daniel Francis Daley * Kingston, Pa., Jefferson Medical College of Philadelphia, 1915, fellow of the American College of Physicians, member of the American Society of Clinical

Pathologists, served the Mercy Hospital, Wilkes-Barre, in various capacities, aged 49, died, April 24, in the Nesbitt Memorial Hospital, of chronic myocarditis

William Wallace Behlow * Surg. Lieutenant Commander, U. S. Navy, retired, Palo Alto, Calif., Harvard University Medical School, Boston, 1912, entered the navy in 1917 and retired in 1931, fellow of the American College of Physicians, aged 50, died, April 29, in the Palo Alto Hospital, of tuberculosis and portal cirrhosis of the liver

Clarence La Vergne Boyd, Forest Hills, Pa., Baltimore University School of Medicine, 1903, member of the Medical Society of the State of Pennsylvania, aged 56, died, April 20, in the Homeopathic Hospital, Pittsburgh, of carcinoma of the fingers on the left hand due to exposure to x-rays, and metastasis to the left axilla

Richard L. Foster, Danville, Ky., Hospital College of Medicine, Louisville, 1900, member of the Kentucky State Medical Association, past president of the Boyle County Medical Society, formerly on the staff of the Danville and Boyle County Hospital, aged 66, died, April 27, of angina pectoris

William Prentice Farrington * Munday, Texas, Vanderbilt University School of Medicine, Nashville, Tenn., 1904, past president of the Baylor-Knox-Haskell Counties Medical Society, aged 55, died, April 17, in the Wichita Falls Clinic-Hospital, Wichita Falls, of melanocarcinoma and cholecystitis

Franklin Pierce Farwell, Galeton, Pa., Jefferson Medical College of Philadelphia, 1906, member of the Medical Society of the State of Pennsylvania, county medical director, aged 58, died, April 24, in the Warren (Pa.) State Hospital, of bronchopneumonia, chronic myocarditis and arteriosclerosis

Green B. Gillespie, Covington, Tenn., Vanderbilt University School of Medicine, Nashville, 1875, Confederate veteran, formerly bank president, and member of the city school board, was president of the county board of health, and county health physician, aged 92, died, April 15, of myocarditis

John Oscar Elrod * Forsyth, Ga., Atlanta College of Physicians and Surgeons, 1901, past president of the Medical Association of Georgia, member of the state board of medical examiners, fellow of the American College of Physicians, aged 59, died, April 21, in a hospital at Macon

Charles Mayer Franklin, La Fayette, Ind., University of Pennsylvania Department of Medicine, Philadelphia, 1881, formerly professor of psychiatry at the Woman's Medical College of Baltimore, aged 82, died, April 19, of malignant disease of the prostate and cerebral hemorrhage

Hermann Goldenberg * New York, Ludwig-Maximilians-Universität Medizinische Fakultät, München, Bavaria, Germany, 1886, member of the American Dermatological Association, on the staffs of the Bronx and Mount Sinai hospitals, aged 74, died, April 1, of cerebral thrombosis

Ralph Freeman, Hoschton, Ga., University of Georgia Medical Department, August, 1909, member of the Medical Association of Georgia, formerly mayor of Hoschton, member of the city council and board of education, aged 53, died suddenly, April 13, of heart disease

Harlan Page Bowman, Greensboro, N. C., University of Tennessee Medical Department, Nashville, 1894, member of the Medical Society of the State of North Carolina, aged 67, died, April 7, in the Clinic Hospital, of cholecystitis, hypertension and cerebral hemorrhage

Arthur Myers Gibbs * Hamburg, Ark., University of Arkansas School of Medicine, Little Rock, 1930, formerly secretary of the Ashley County Medical Society, county health officer, aged 32, died, April 17, in a hospital at Bastrop, La., of carcinoma of the stomach

Arthur Garfield Frey * Chicago, Northwestern University Medical School, Chicago, 1911, fellow of the American College of Surgeons, on the staffs of the Lutheran Memorial and Grant hospitals, aged 53, died, April 8, of coronary occlusion and arterial hypertension

Winfield Scott DeVausney, Newark, N. J., Medico-Chirurgical College of Philadelphia, 1899, member of the Medical Society of New Jersey, aged 58, died, April 6, in the Presbyterian Hospital as the result of injuries received when struck by an automobile

Parvin Douglas Gillum * Owensboro, Ky., University of Louisville Medical Department, 1905, member of the Radiological Society of North America, on the staff of the Owensboro City Hospital, aged 55, died, April 12, of cardiorenal vascular syndrome

George Kuester Cotton * Denver, University of Colorado School of Medicine, Denver, 1929, member of the staffs of the

Colorado and Denver General, Mercy, Children's, St Luke's, Presbyterian and Beth Israel hospitals, aged 34, died, April 26, of pneumonia

Clark Eli Beede ☉ David City, Neb., University of Nebraska College of Medicine, Omaha, 1918, formerly secretary of the Butler County Medical Society, aged 42, on the staff of the David City Hospital, where he died, April 12, of acute nephritis

Eugene S. Dalton ☉ Brooklyn, Syracuse University College of Medicine, 1908, fellow of the American College of Physicians, aged 54, on the staff of the Methodist Episcopal Hospital, where he died, suddenly, April 19, of coronary thrombosis

Albert Franklin Fitch, Flushing, N. Y., College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1893, died, April 25, of subdural hemorrhage following a fall and pulmonary tuberculosis

Charles William Heitzman ☉ Muskogee, Okla., Tulane University of Louisiana Medical Department, New Orleans, 1899, aged 67, on the staff of the Oklahoma Baptist Hospital, where he died, March 8, of hypochromic anemia

Albert A. Dixon, Pensacola, Fla., Louisville (Ky.) National Medical College, Medical Department State University, 1910, aged 57, died, April 28, in the Pensacola Hospital, of cerebral hemorrhage and arteriosclerosis

Jacob M. Gross, York, Pa., Jefferson Medical College of Philadelphia, 1872, member of the Medical Society of the State of Pennsylvania, formerly bank president in Dover, aged 93, died, April 6, of cerebral hemorrhage

Charles S. Burnside, Marion, Ohio, Starling Medical College, Columbus, 1897, member of the Ohio State Medical Association, formerly county coroner, aged 68, died, April 1, of secondary anemia and acute nephritis

Samuel Clifford Wood, Leesburg, Fla., University of Georgia Medical Department, Augusta 1904, member of the Florida Medical Association, health officer of Leesburg, aged 60, died, March 30, of pneumonia

James Edward Bell, Baltimore, University of West Tennessee College of Medicine and Surgery, Memphis, 1915 Meharry Medical College, Nashville, Tenn., 1918, aged 46, died, April 25, of lobar pneumonia

George Laurin Dewey, Cedar Rapids, Neb., Tulane University of Louisiana Medical Department, New Orleans, 1900, aged 74, died, April 22, of a malignant growth of the right lung and bronchogenic carcinoma

Walter Scott Grant ☉ Brooklyn, University of Pennsylvania Department of Medicine, Philadelphia, 1899, on the staff of the Bushwick Hospital, aged 64, died, April 10, of carcinoma of the lungs and rectum

Samuel E. Sanger, Monrovia, Calif., Hahnemann Medical College of the Pacific, San Francisco, 1908, aged 72, died, March 2, of comminuted fractures of the leg with exhaustion and hypostatic pneumonia

John Franklin Gardner ☉ Montgomery, Pa., Medico-Chirurgical College of Philadelphia, 1899, past president of the Lycoming County Medical Society, aged 59, died, April 7, of coronary thrombosis

Edgar Garland Ferrier, Oak Forest, Ill., Jenner Medical College, Chicago, 1916, on the staff of the Cook County Tuberculosis Hospital, aged 57, died suddenly, April 16, in Chicago, of chronic myocarditis

Fannie Davis, Oil City, Pa., Western Pennsylvania Medical College, Pittsburgh, 1906, member of the Medical Society of the State of Pennsylvania, aged 75, died, April 28, of coronary thrombosis

James Erman Bridgwater, Albany, Ore., St. Louis University School of Medicine, 1910, formerly mayor of Creswell, aged 53, died, April 28, in the Albany General Hospital, of duodenal ulcer

Frederick Ira Acheson, San Diego, Calif., University of Kansas School of Medicine, Kansas City, 1906, aged 70, died, April 26, of arteriosclerosis, coronary sclerosis and acute purulent bronchitis

William Willis Durden, Columbus, Miss., College of Physicians and Surgeons, Medical Department of Columbia College, 1872, Confederate veteran, aged 92, died, April 18, of a hip fracture

Willis J. Bryant, Summerville, Ga., Vanderbilt University School of Medicine, Nashville, Tenn., 1882, member of the Medical Association of Georgia, aged 82, died, April 5, of hemiplegia

George Lincoln Broadrup, Lancaster, Pa., College of Physicians and Surgeons, Baltimore, 1891, aged 73, died April 28, in the Lancaster General Hospital, of coronary occlusion

John Edwin Beck ☉ Tulare, Calif., College of Physicians and Surgeons of San Francisco, 1905, on the staff of the Tulare Hospital, aged 63, died suddenly, April 8, of coronary occlusion

John Stannard Campbell, Cleveland, Western Reserve University Medical Department, Cleveland, 1883, aged 80, died, April 18, in Painesville, Ohio, of lobar pneumonia and phlebitis

John Lewis Davis ☉ Portland, Maine, Medical School of Maine, Portland, 1906, head physician of the Jewish Home for the Aged, aged 53, died, April 13, of coronary thrombosis

Joseph L. Clemmer, Gentry, Ark., Kansas City (Mo.) Medical College, 1901, member of the Arkansas Medical Society, aged 59, died, April 1, of coronary occlusion

Le Roy A. Cockfield, Bermuda, La., Tulane University of Louisiana Medical Department, New Orleans, 1908, aged 52, died, April 4, of myocarditis and diabetes mellitus

Oren Ellsworth George, Cleveland, University of Wooster Medical Department, Cleveland, 1889, aged 71, died April 8, of monocytic leukemia and cholelithiasis

Augusta Stone, Los Angeles, California Eclectic Medical College Los Angeles, 1913, aged 68, died, March 29, in Glendale, of arteriosclerosis and cerebral hemorrhage

Frederick Mears Gedney, San Francisco, Cooper Medical College of San Francisco 1903, aged 59, died, March 26, in the Franklin Hospital, of coronary thrombosis

William Thomas Boon ☉ Philadelphia, University of Pennsylvania Department of Medicine, Philadelphia, 1897, aged 63, died, April 14, of coronary occlusion

John Franklin Crawford, Clay, Ky., University of Louisville Medical Department 1901, formerly mayor, aged 59, died suddenly, April 17, of coronary occlusion

William Tilton Crawford, Fowler, Calif., Western Pennsylvania Medical College, Pittsburgh, 1889, aged 73, died, April 11, of cerebral hemorrhage

Sterling O. Hays, Dallas, Texas, Baylor University College of Medicine, Dallas, 1904, aged 67, died suddenly, March 29, of coronary occlusion

Sol D. Ebersole, Chicago, Hahnemann Medical College and Hospital, Chicago, 1891, aged 71, died, April 10, of lobar pneumonia and nephritis

John Woodward Pierce, Brooklyn, Long Island College Hospital, Brooklyn, 1894, aged 67, died suddenly, March 26, of coronary thrombosis

Kate Whipple Cory, Geneva, Ohio, Homeopathic Hospital College, Cleveland, 1880, aged 87, died, April 23, of cerebral hemorrhage

Zia Mabsut Bagdadi, Augusta, Ga., Chicago College of Medicine and Surgery, 1911, aged 54, died, April 11, of coronary thrombosis

Charles A. Chumbley, Oakland City, Ind., Kentucky School of Medicine, Louisville, 1902, aged 69, died, March 15, of acute gastritis

Harvey F. Bean, Mountainville, Pa., Jefferson Medical College of Philadelphia, 1889, aged 70, died, April 25, in Bath, of heart disease

John Kennerly Farris Jr., Manchester, Tenn., University of Nashville Medical Department, 1899, aged 70, died, April 1, of gastric ulcer

Frank F. Bernard, Boston, College of Physicians and Surgeons, Boston, 1897, aged 72, died, April 19, of cerebral hemorrhage

Jane Roney Husted, Columbus, Ohio, Ohio Medical University, Columbus, 1901, aged 68, died, April 24, of heart disease

Hinton James Eve ☉ Augusta, Ga., University of Georgia Medical Department, Augusta, 1899, aged 59, died, April 27

Louise Acres, Western Springs, Ill., Woman's Hospital Medical College, Chicago, 1890, aged 78, died, April 27

Fred H. Gault, Lewisburg, Tenn., Chattanooga Medical College, 1894, aged 65, died, April 4, of heart disease

Lewis J. Blanton, Atlanta, Ga., Atlanta Medical College, 1898, aged 66, died, April 4, of cerebral hemorrhage

Charles M. Greiner, Detroit, Detroit College of Medicine, 1897, aged 70, died, April 8, of coronary thrombosis

Bureau of Investigation

HELENA RUBINSTEIN INVADES "HEALTH FIELD"

"Palace of Beauty" Combines Physical Examination,
Milk Bath, Ultraviolet Rays, Manicure
and Latest Hair-Do

Mme Helena Rubinstein
715 Fifth Avenue
New York
Dear Helena

A Florida physician has just sent the Bureau of Investigation a copy of your advertisement, "One Thrilling Day at 715". He wants to know about the Rubinstein health treatments.

Naturally, the medical profession is interested in all health programs. Yours seems so unusual, we are anxious to obtain

ONE THRILLING DAY AT 715 WILL CHANGE THE STORY OF YOUR LIFE

It began with Eve. And since then there has scarcely been a woman born who has not at one time or another dreamed of stepping into the pages of a fairy tale into an enchanted world of glamour and beauty where a magic palace awaited her and a series of thrilling adventures that ended in her being turned into a fairy princess.

Today a woman who has herself dreamed this dream is for the first time making it come true for the women of America.

Her name is known around the world. It is Madame Helena Rubinstein.

As soon as the portals of her new "palace of beauty" close behind you, a day of thrilling adventure begins.

First you have a physical examination by a physician. Then to the Beauty Gym for a workout.

Now for a massage on the exclusive Helena Rubinstein sano therm table which generates penetrating infra red rays.

Enter next—the Sun Ray Clinique where a shimmering ceiling sends ultra violet rays to give you an even coat of tan as you lie on a warm bed of real white sand.

Oh luxury of luxuries now is yours a Pasteurized Milk Bath with its breakers of foam exhilarating relaxing.

Now your luncheon is served—from Helena Rubinstein's new Health Bar.

After an examination by the Derma Lens a face treatment follows consisting of the Hormone Creams or the new Beautilift Masque or whatever meets your individual requirements. Then comes a hand massage manicure and a ravishing make up. Finally Josef gives you a Balsam Oil Permanent and the latest hair-do photo-cabled from Paris.

You walk out of Helena Rubinstein's palace of beauty no longer just a charming woman but a modern princess. © 1937 H. R. Inc.

Helena Rubinstein
715 FIFTH AVENUE

princess might be the start of a psychosis. Maybe it would be advisable to include a mental examination along with a physical one.

As you announce, "First you have a physical examination by a physician. Then to the Beauty Gym for a workout," it would appear that the mental examination is omitted.

"Now for a massage on the exclusive Helena Rubinstein sano-therm table which generates penetrating infra-red rays." You've got us there, Madame. What is a sano therm table? We have consulted several prominent physicians, specialists in physical therapy and physical therapy devices, and none of them have ever heard of the "exclusive Helena Rubinstein sano-therm table." We note that you say it "generates penetrating infra-red rays." But so does a hot brick or a hot potato. According to "The Modern Materia Medica" (second edition), "Sanotherm is a mixture for making oxygen baths, which in addition to the usual constituents, contain a radio-active substance (pitchblende) and pine-needle extract." Obviously, this is not the "exclusive Helena Rubinstein sano-therm."

"Enter next—the Sun Ray Clinique where a shimmering ceiling sends ultra-violet rays to give you an even coat of tan as you lie on a warm bed of real, white sand." And then, "Oh, luxury of luxuries now is yours a Pasteurized Milk Bath with its breakers of foam, exhilarating, relaxing." For the benefit of interested physicians, we should like to know if the Rubinstein clinical records show more beneficial results with pasteurized milk than with certified or raw. Offhand, we would think raw milk more appropriate.

"Now your luncheon is served—from Helena Rubinstein's new Health Bar." As you give no sample menus and as the word "bar" always brings to mind cocktails, we are wondering if you are serving the real thing or those Benjamin Gayelord Hauser concoctions of carrot juice and celery juice.

"After an examination by the Derma-Lens, a face treatment follows, consisting of the Hormone Creams or the new Beautilift Masque or whatever meets your individual requirements." In an endeavor to answer our inquirer, we called on several nationally known dermatologists (dermatologists, Helena, are graduates in medicine who specialize in diseases of the skin) to ask if they used the Derma-Lens, and we are unable to find any who use the device.

After the Derma-Lens examination "comes a hand massage, manicure, and a ravishing make-up. Finally Josef gives you a Balsam Oil Permanent and the latest hair-do photo-cabled from Paris." Madame, do you think Josef and the doctor could get together and do anything for a patient with paramnesia?

"You walk out of Helena Rubinstein's 'palace of beauty' no longer just a charming woman but a modern princess."

Dear Helena, our experience with princesses is somewhat limited. Most of them were hardly ravishing. But those princesses had something else to do besides putting in a day at 715. But really, Helena, the thing that is worrying us is this: "What does Cinderella do next morning, when her fairy coach has turned again into a pumpkin, when her sun-tan has begun to fade, and when she turns pale and weak at the sight of the bill?" In the words of Hashimura Togo, we inquire to know

Sincerely yours,
THE BUREAU OF INVESTIGATION

VAN-TAGE

Food and Drug Administration Declares "Van-Tage"
Adulterated and Misbranded

"Van-Tage," a "patent medicine," product of Gilbert H. Mosby, Van-Tage Medicine Company, Inc., Los Angeles (Bureau of Investigation, THE JOURNAL, Nov 12, 1936, p 1655), has been declared sold under false and fraudulent claims, according to a May 1937 report of the Food and Drug Administration.

Feb 18, 1936, the United States attorney for the District of Utah, acting on a report by the Secretary of Agriculture, filed a libel praying seizure and condemnation of thirty dozen bottles of Van-Tage at Salt Lake City, Utah, alleging that the article had been shipped in interstate commerce from Los Angeles and was misbranded in violation of the Food and Drugs Act as amended. May 28, 1936, no claimant having appeared,

some first-hand information. The advertisement says "It began with Eve." Now, Helena, so many things began with Eve, including "original sin," that we don't think you should blame poor Eve for any more sins unless you have documentary evidence to back it up.

But to get on with the advertisement "and since then there has scarcely been a woman born who has not at one time or another dreamed of stepping into the pages of a fairy tale." Sigmund Freud could help your clientele out on this dream business. An unfulfilled wish to become a fairy

a judgment of condemnation was entered and it was ordered that the products be destroyed. According to the government report, analysis showed the article to consist essentially of potassium iodide (0.2 Gm per hundred milliliters), pepsin (0.1 Gm per hundred milliliters) and extracts of plant drugs including aloe, glycerin, water and flavoring material, preserved with salicylic acid.

Correspondence

ERYTHEMA NODOSUM

To the Editor—In THE JOURNAL, May 1, is an editorial entitled "Causative Factors in Erythema Nodosum." The editorial is based chiefly on a recent article in the *Archives of Internal Medicine* by W. W. Spink, who reported a critical study of ten cases of erythema nodosum in which only one gave evidence of tuberculosis. The relationship to streptococcal infections was particularly stressed. His conclusion was that "erythema nodosum appears to be a nonspecific inflammatory reaction of the skin to a variety of bacterial, toxic and chemical agents."

It would seem timely to draw attention to the fact that in the San Joaquin Valley in California there is endemic a relatively mild febrile disease which is characterized by a bad cold or bronchopneumonia, associated with erythema nodosum. The patients usually recover promptly and, apparently, without complications. The disease is often diagnosed as erythema nodosum and is popularly known in the valley as "San Joaquin Valley fever" or "desert fever." In a large percentage of the cases which have been studied at the Stanford Medical School in San Francisco and in the County Health Department of Kern County at Bakersfield, the sputum contains typical sporulating and nonsporulating spherules of *Coccidioides*, from which pure cultures of the fungus *coccidioides* may be obtained and proved virulent by guinea-pig inoculation. In one instance, the case of a small child, I obtained positive results in the washings, which were obtained by gastric lavage. Intradermal *coccidioidin* tests are violently positive.

These observations add another important disease to the list of those which may be associated with erythema nodosum. There seems to be no doubt that we are dealing with the symptom complex of primary acute infection with fungus *coccidioides*.

ERNEST C. DICKSON, M.D., San Francisco

Professor of Public Health and Preventive
Medicine, Stanford University School of
Medicine

VITAMIN K

To the Editor—It seems unfortunate that the recent editorial on the antihemorrhagic factor in foods (THE JOURNAL, May 15, p. 1717) failed to consider certain researches bearing directly on the subject of vitamin K, for obviously at this stage in the study of this new vitamin all results obtained by carefully executed research are apt to be helpful in determining its function and possible therapeutic usefulness.

Vitamin K appears definitely to be a food accessory factor required for the synthesis of prothrombin. By means of a new quantitative method for prothrombin (*J Biol Chem* 109 [May] 1935) I was able to follow the changes in this important clotting factor in chicks deprived of vitamin K (*Am J Physiol* 118:260 [Feb.] 1937). In some of the chicks, a drop of 50 per cent in the prothrombin concentration was observed as early as the fourth day. When the prothrombin fell below 20 per cent, active hemorrhage readily occurred. Naturally one is interested in knowing whether vitamin K is important in human physiology and whether it may be of value in such conditions as hemophilia. Drs. Bancroft, Stanley-Brown and I (*Am J Med Sc* 190:501 [Oct.] 1935) found that the prothrombin content of hemophilic blood was the same as that

of normal blood. We also obtained evidence that the prothrombin in hemophilia is activated as readily by thromboplastic substance as is the prothrombin in normal blood. Thus, one drop of my highly active thromboplastic preparation when added to 1 cc of freshly drawn hemophilic blood caused coagulation in twenty-four seconds, whereas the control containing no added thromboplastic substance remained fluid for thirty-eight minutes. These facts strongly suggest that the prothrombin is not the factor responsible for the delayed coagulation in hemophilia, and it is not surprising therefore that Dam and his associates (*Biochem J* 31:22 [Jan.] 1937) failed to find any beneficial effects accruing from the use of vitamin K in hemophilia.

Vitamin K may perhaps prove to be of real benefit in the treatment of the hemorrhagic diathesis of obstructive jaundice. We found a definite, and occasionally a marked, decrease in the concentration of prothrombin in various types of biliary obstruction. One can conclude that the cause of bleeding in jaundice is a prothrombin deficiency. In my recent article I have offered a possible explanation for this decrease in prothrombin. The jaundiced patient presents peculiarly suitable conditions for the development of a deficiency of the fat soluble vitamins. The prolonged restricted low fat diet, and the poor absorption of fat soluble material due to the absence of bile in the intestine can conceivably so reduce the supply of vitamin K that the stored reserve is no longer adequate, whereupon the prothrombin begins to diminish. If this hypothesis is correct, vitamin K is therapeutically indicated. In fact it is not improbable that small amounts of powdered alfalfa, a substance particularly rich in the prothrombin vitamin, and bile salts administered orally may perhaps effectively prevent the postoperative hemorrhage encountered in certain jaundiced patients.

ARMAND J. QUICK, M.D., Milwaukee

Associate Professor of Pharmacology,
Marquette University School of Medicine

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

CONCENTRATED MILK FOR CAMPS

To the Editor—I am camp surgeon in charge of 100 men in what is probably the most isolated spot in the continental United States. This camp will be shut off from civilization for at least four months during the freeze. After December 1 we shall have no means of transportation to this island from the mainland 60 miles away except by radio and plane for emergency when possible. During these four months we shall have no fresh meat except the frozen type and no fresh fish, fruits or milk. We shall have assorted dried and canned fruits and vegetables but no forms of citrus fruits. We are using ordinary canned condensed milk which I believe is suitable only for tea and coffee. I have recommended Borden's Eagle Brand Evaporated Milk and canned grape fruit which may contain some antiscorbutic vitamins. Some camps have used a powdered form of milk for cooking with which I am not familiar. Can you make any comments or suggestions on what brands and forms of milk and canned fruits will be suitable for the needs of these men for the winter?

M. D. Michigan

ANSWER—For the conditions described there are several excellent forms of concentrated milk available, including powdered whole milk, unsweetened evaporated milk and sweetened condensed milk. These products are nutritionally equivalent to ordinary milk except for vitamins B₁ and C, and they are clean and safe. Evaporated and condensed milks are obtainable in 14½ and 16 ounce cans, respectively. Powdered milks such as Klrim (dried whole milk), on the other hand, can be purchased not only in one pound sealed cans but also in 50 pound containers and in larger quantities at material savings. This dried milk can be stored for considerable periods and reliquified with pure water when needed. Powdered and condensed milks are, of course, low in vitamin C, and evaporated milk has none of this vitamin, therefore it should be supplied in the diet by

means of canned tomatoes or tomato juice, which is rich in this vitamin. This food factor may also be supplied by canned citrus fruits or fruit juices, any of the standard brands of which should be satisfactory.

MIGRAINE

To the Editor—Can you suggest any treatment for a case of migraine that will not respond to ergotamine tartrate (gynergen)? The patient aged 38 has three children 13, 5 and 4 years of age. There have been no miscarriages. The Wassermann reaction is negative. Attacks of migraine started four years ago after the last childbirth. They used to be premenstrual but now occur three or four times a month. Symptoms include occipital headache, pain behind and in the right ear, nausea and vomiting, weakness and inability to walk. Skull roentgenograms are negative, the ears are normal, the eyes are normal, and the patient is in perfect health between attacks. I have used theelin, theelin emmenin and so on intermenstrually and gynergen with morphine during the attacks with poor results. I have read O'Sullivan's article in *THE JOURNAL* of Oct 10, 1936, but cannot get any response. I am about to suggest pregnancy or hysterectomy, as the woman is a burden in this state. Would hysterectomy or oophorectomy produce a cure? I may add that there are religious objections to surgery. Please omit name.

M D, Ontario

ANSWER—From the description there is some doubt as to whether this is an instance of the usual type of migrainous attack of headache. It is neither ophthalmic nor ophthalmoplegic migraine. It may be a symptomatic headache due to organic disease of the brain. The patient's first attack occurred at 34 years of age, which is late for the onset of true hemicrania. It is suggested that a detailed neurologic and ophthalmologic examination be made for the purpose of finding objective evidence of organic brain disease. If no such evidence is found the patient might be given a two or three weeks course of potassium or sodium bromide and sodium salicylate, 1 Gm of each three times daily. At the end of this period fluid extract of cannabis should be given, starting with three drops three times daily and increasing the dose by one drop daily until the dosage is eleven drops three times a day. Then the dose is decreased by one drop daily until it reaches three drops. The dose is then increased to eleven drops and again decreased to three drops. This process is continued indefinitely if favorable results occur. If favorable results have not occurred at the end of two months, this treatment should be discontinued. In association with this therapy the patient should be advised to get sufficient physical and mental rest, should be kept free from excitement or worries, and should not overeat. Hysterectomy or oophorectomy, it is believed, would not stop attacks of migraine.

SENSITIVITY TO ARSPHENAMINE

To the Editor—I have recently had a severe case of dermatitis exfoliativa following the sixth injection of 0.6 Gm of neoarsphenamine given for congenital syphilis in a woman 25 years of age. Are any specific remedies being advanced in this condition? The only medical measure so far employed has been sodium thiosulfate which has proved very disappointing. Please omit name.

M D Michigan

ANSWER—Sodium thiosulfate, though of great value in most of these cases, fails signally in some of them. The reason for this is not known. In such cases quinine may be used. It has long been one of the most reliable helps in the treatment of exfoliative conditions. Starting with a small dose to discover whether any sensitization to the drug exists, one can increase the dose until signs of saturation, ringing in the ears or gastrointestinal disturbance make their appearance. Some patients with exfoliative dermatitis are able to take with great benefit enormous doses of quinine.

Calcium may be of great assistance. It is possible that the milk diet advocated by some authorities acts largely because of its content of available calcium. Calcium gluconate in the muscles or veins may be required.

The blood should be watched for signs of agranulocytosis, one of the most serious accompaniments of cases due to arsphenamine. General supportive and protective treatment is of great importance. The diet should be digestible and nutritious, with attention to vitamins and avoidance of condiments. Constipation must be avoided.

The skin must be protected from irritation in all ways possible. Scratching is the chief danger in this respect. The ear canal should be cleansed with warm boric acid solution, and a watch should be kept for furunculosis. The mouth and the conjunctival sac, if inflamed, must be given cleansing and soothing treatment. The air of the room should be warm and moist. Chilling, so apt to occur in any generalized dermatitis, must be avoided.

The patient must be protected from exposure to infection of the respiratory tract. Poole and Wehger, however, have shown

that fatalities from exfoliative dermatitis seem to be due frequently to an exfoliative condition in the air passages rather than to pneumonia. A similar condition in the kidneys was found by these authors. The urine should be examined during the course of the disease. (Poole, A. K., and Wehger, R. T. Fatalities in Exfoliative Dermatitis, *THE JOURNAL*, March 10, 1934, p. 745.)

One of the most valuable aids in the treatment of these cases is the colloid bath. Oatmeal two or three cupfuls, should be boiled in a gauze bag for five minutes. A cupful of sodium bicarbonate should be stirred into the bath water, which should be about blood heat. Then the bag of oatmeal should be stirred about in the water and squeezed gently. The patient's knees should be covered by towels frequently wet with the bath water, which should be kept at about 98 F by the addition of small amounts of hot water. At first ten or fifteen minutes should be the limit two or three times a day, but, if agreeable and beneficial, the length and frequency may be increased. During a longer bath, cool cloths should be kept on the head and the patient must be protected from drafts. A nurse should be constantly in attendance.

On removal from the bath, the skin should be patted partly dry and an ointment applied either zinc oxide ointment or 10 per cent boric acid in rose water ointment or petrolatum. Furuncles should be watched for and treated promptly.

The warning given by Stokes against interference with foci of infection in the teeth, tonsils or elsewhere during the course of an exfoliative dermatitis must be heeded, for such interference is dangerous. He cites a case in which chance recovery was lost by too early an attack on such foci. They must be left until the dermatitis is well cleared before operations can be undertaken with safety. (Stokes J. H. *Modern Clinical Syphilology*, ed 2, Philadelphia, W. B. Saunders, 1934, p. 491.) Stokes's outline has been followed in this summary.

If the dermatitis in certain areas is slow to resolve, small doses 37 or 70 roentgens, of unfiltered rays each week will usually speed up recovery and stop the itching.

EFFECTS ON CHILD OF USE OF MORPHINE AND CALOMEL IN LACTATING MOTHER

To the Editor—A patient was delivered of a normal apparently healthy baby which seemed to do all right in every way until after the mother was given a hypodermic of morphine for the relief of pain from hemorrhoids. The baby was allowed to nurse and following this became somewhat drowsy. Later the patient was given broken doses of calomel and the baby developed a diarrhea. I would appreciate your opinion as to the action of the morphine and calomel on the child.

M D, North Carolina

ANSWER—Shute and Davis (*Surg, Gynec & Obst* 57:727 [Dec] 1933) studied babies born of mothers who had received morphine during labor. The babies showed positive tests for morphine on their stools, most readily from the fourth to the seventh day after birth. These authors say "Reiche, in working on dogs, demonstrated that morphine given to the mother does not appear in her milk, and cites Walter's corroborative work. Our work shows that morphine appears in the stools of both breast-fed and wholly bottle-fed infants in an identical way, thus substantiating Reiche's experiments." Terwilliger and Hatcher (*Surg, Gynec & Obst* 59:823 [April] 1934) studied the question of elimination of morphine in the human milk in a morphine addict who received 128 mg of morphine sulfate daily for many weeks after her baby was born. Not a trace of morphine could be detected in the milk of this woman. These authors examined the milk of a normal woman seven and a half hours after the administration of 16 mg of morphine sulfate and they believe that the milk may have contained a trace of morphine. Talbot (*Am J Dis Child* 7:445 [June] 1914) felt certain that morphine had not been found in human milk up to the time he wrote his article. Kvit and Hatcher (*Am J Dis Child* 49:900 [April] 1935) examined the milk of a woman four hours after she had received 16 mg of morphine sulfate. The milk contained at most a trace of morphine.

Shute and Davis point out that infants in the uterus can tolerate large doses of morphine over a period of days or even months without showing any unusual effects. Likewise the literature contains numerous references concerning the tolerance of very young infants for opiates. Mason reported a 56 hour old baby who tolerated 0.008 Gm. of morphine, and Kayser observed a 10 day old child who tolerated 0.01 Gm. of morphine.

On the other hand De Lee (*Principles and Practice of Obstetrics* ed 5, p. 229) says "Drugs often reappear in the milk. This has been known since Hippocrates, in connection with cathartics. One may, in order to purge the infant give the mother the cathartic. Opium has caused narcosis

of forty-three hours in the baby Iron, arsenic, iodine, lead and mercury are well known to pass over"

Holt (The Diseases of Infancy and Childhood, New York, D Appleton & Co) says that the effect of opium in the milk is "inconstant, although it is possible, when the milk is poor, for toxic symptoms to be produced when full doses are given to the mother A fatal case is on record in a child a few days old"

Little is known about the transmission of calomel through the milk It has long been believed that mercury when administered to the mother is in part eliminated through the milk One of the ways of treating a baby born of a syphilitic mother was to have the baby nurse at the breasts of its mother who was receiving antisyphilitic treatment, particularly mercury Nevertheless as Bucura (*Ztschr f exper Path u Therap* 4 398, 1907) pointed out years ago, extremely few drugs have been found in the milk with certainty Last year in Kwit and Hatcher's study of the excretion of drugs in human milk they examined milk for morphine, codeine, salicylic acid, phenolphthalein, barbitol, sodium bromide and potassium iodide They concluded that none of the drugs except sodium bromide were present in the milk in an amount sufficient to indicate that the continued use of such milk would injure a normal nursing child

INJECTION TREATMENT OF VARICOSE VEINS

To the Editor—It has become my duty to supervise the injection therapy of a group of patients afflicted with varicose veins of all degrees of duration and extent In the course of my reading regarding the choice of a sclerosing agent and the technic of injection I was able to decide on a 5 per cent solution of sodium morrhuate but the variety of injection technics left me completely at sea By this I mean that the use of the tourniquet is advocated by some and scoffed at by others Authorities differ as to whether the patient should be upright or lying down with the leg elevated Should one or several veins be injected at one sitting was another moot point I would appreciate your advising me on these sources of equivocation and discuss for me the treatment nonsurgical of varicose veins, uncomplicated complicated by eczema and complicated by ulcer referring to the course of injection therapy to be followed and not the general care of such conditions Please omit name

M D, California

ANSWER—It is recommended that the correspondent obtain from the American Medical Association a pamphlet issued by the Committee on Varicose Veins The subject matter was demonstrated at the Philadelphia session in 1931 Generally speaking, the sclerosing solution should be in contact with the intima of the injected vein in as concentrated a solution and for as long a time as possible It is always preferable to inject in a horizontal position because of the active vasovagal reflexes of some patients, resulting in loss of consciousness Whether a tourniquet or finger pressure is used to keep the solution in place is relatively unimportant What is important is the slowing down or standstill of venous return, so that the solution may sear the intima These and other questions are all answered in the pamphlet which represents the joint experience of a number of men throughout the country

TESTS OF CYSTINE IN NAILS—USE OF SULFUR FOR IMPROVING NAILS

To the Editor—Are there any reliable laboratories giving tests for the cystine content of the nails? If so are they of any significance in treating drying and ridging of the finger nails with the use of forms of sulfur intramuscularly?

STANTON S ENDS JR M D Middlebury Vt

ANSWER—M X Sullivan and W C Hess and others have shown that sulfur in the nails is almost entirely in protein combination as cystine which contains 26.7 per cent of sulfur They describe a procedure of analysis of the finger nail clippings for cystine (*J Bone & Joint Surg* 16 185 [Jan] 1934) used in the course of their investigations of the cystine content of the finger nails in arthritis J V Klauder and Herman Brown (*Arch Dermat & Syph* 31 26 [Jan] 1935) report the results of studies of the sulfur content of the nails in diseases or abnormalities of the nails The sulfur content of the nails in their investigations was determined by the method of Stockholm and Koch (*J Chem Soc* 45 1953, 1923) In their article Klauder and Brown detail their observations on the effect of hydrolyzed wool in the treatment of patients with pathologic nails and the effect of such treatment on the sulfur content of the nails

Hydrolyzed wool (Brown, Herman, and Klauder, *J V Arch Dermat & Syph* 27 584 [April] 1933) was administered orally two teaspoonsful to an adult and one teaspoonful to a child, three times daily, and continued for about three months The cystine content of hydrolyzed wool was about 1.5 Gm in 32 cc Clinical improvement was apparent only in patients

with congenital dystrophy of the nails The ingestion of hydrolyzed wool may or may not increase the sulfur content of pathologic nails

Klauder and Brown conclude from their experiments that "it does not appear that determination of the sulfur content of the nails is of any value in the study of diseased nails"

The use of sulfur intramuscularly should not offer any greater hope of response and would entail great expense in a therapeutic procedure of doubtful efficacy In their earlier article Klauder and Brown further commented that "it appears more pertinent to utilize all the constituents of keratin" Sulfur orally has been used by some of the older writers

The possible role of external irritants used to clean and polish the nails, contacts in the daily routine of housework, or the patient's occupation, and the possible role of associated or pre-existing cutaneous or systemic disease should be ruled out as contributory factors to the "drying and ridging of finger nails"

Hypovitaminosis as an etiologic factor should be considered, and the administration of vitamins B and D may clear up the condition

NERVE IRRITATION FROM FIBROSIS AFTER OPERATION ON WRIST

To the Editor—Dec 4 1936, I was in an automobile accident and sustained a severe laceration of the right wrist This laceration is on the flexor surface and runs diagonally all the way across the wrist It is situated about 1 inch above the junction of the wrist and the thumb The radial artery and median nerve were completely severed also the flexor tendons to the middle and index fingers Sensation has not yet started to return although I am able to flex my fingers to the extent of about half closing my fist Beginning about December 11 I developed severe needle-like constant pains in the middle joints of my ring, index and middle fingers and the terminal portions of the thumb I could not control this pain even with the use of morphine Heat gave best relief but only partial As time has elapsed and with increase of exercise of my fingers the pain has completely left the ring finger but with regard to the other fingers the pain has now moved out to the terminal phalanges Would you please give me some idea as to when I can expect tactile sensation to return? Also in your opinion what is the cause of the constant pain I am having? May I also state on this point that I was given one opinion that this pain may be due to irritation of nerve endings in the scar With this idea in mind the area about the scar was infiltrated with procaine hydrochloride but this procedure had no effect on lessening the pain Do you think that impairment of circulation would cause this pain since to me it has the same feeling as if one would place a tight band around a finger cutting off the circulation At present this pain is only in the terminal phalanges If the pain is due to impairment of circulation what can I do about it besides heat and massage? How long will it be before this will leave? I would appreciate it if you could supply me with information regarding injuries of this kind Needless to say it is a very important problem to me as far as my future is concerned as a physician and surgeon as to whether I am going to have a useful hand again Please omit name

M D Minnesota

ANSWER—The pain described is characteristic of nerve irritation, and since it developed so soon after the injury the most likely cause would seem to be the irritation of inflammatory reaction and of the fibrosis that follows it

The division of the radial artery and of the sympathetic nerve fibers that surround it does not offer an adequate explanation for the symptoms complained of, since such an injury occurs frequently and the history of subsequent pain such as is described, is very unusual

The important information one would like to have concerning this case is lacking, that is, what was done immediately after the injury to the divided tendons and nerve and, if suture was carried out, the exact technic of operation

ANESTHESIA AND ALLERGIC STATE

To the Editor—Does general anesthesia alter the allergic state? Is it possible to prevent an immediate serum reaction in a hypersensitive patient by the use of anesthesia? Please omit name

M D New Jersey

ANSWER—The query brings up important points, both experimental and clinical In *THE JOURNAL*, Oct 1, 1932, page 1194 appeared a somewhat similar query followed by an answer concluding "It would appear that a general anesthetic is likely to prevent or at least delay anaphylactic shock, if, during anesthesia, foreign protein is injected in a sensitized patient It must be remembered, however, that there are great individual differences in the reactions of animals and also in man, and the apparently favorable effect of anesthesia in preventing shock should not be allowed to displace other precautionary measures which may be taken for its prevention"

Carl A Dragstedt (*THE JOURNAL*, July 27, 1935, p 300) objected strenuously to these conclusions and quoted several authorities to prove that anesthesia in animals does not in the least prevent anaphylactic shock As a matter of fact, Dragstedt

inclines to the belief that anesthesia not only does not diminish anaphylactic shock but may actually increase it. He points out that most of the work on anaphylaxis in dogs has been done under various anesthetics and he himself has used ether, chloroform, paraldehyde, barbital and vinethene, with and without morphine, and often in combination, without any apparent ameliorating effect.

Prof A C Ivy, head of the physiology department of Northwestern University Medical School, agrees with Dragstedt that anesthesia in experimental anaphylaxis does not prevent shock.

Clinically, in man, there is no known comparable piece of work. No one has apparently tried to anesthetize a person during an immediate serum reaction or during a severe constitutional reaction that quickly followed an injection of a protein extract, e g, ragweed pollen or horse dander. The physician gives epinephrine as quickly as possible in such a case and repeats it if necessary. In severe cases he injects it intravenously or even intracardially and he may resort to artificial respiration or other methods of stimulation. But he would not attempt any form of anesthesia. This is strictly contraindicated in such cases.

In long continued cases of bronchial asthma (intractable asthma), anesthesia is sometimes helpful. Ether and oil by rectum are frequently helpful. Complete ether anesthesia for about thirty minutes has also been given severe asthmatic patients, with good results, by I S Kahn (*J Allergy* 6 556 [Sept.] 1935) and by Leon Unger (unpublished), also with benefit. Unfortunately, only temporary relief is obtained but in some cases the anesthesia has apparently been a life-saving procedure.

ACUTE THROMBOPHLEBITIS

To the Editor—An unmarried woman aged 21 became ill at about 9:30 in the morning. Her initial symptom was chills followed several hours later by vomiting. About midafternoon she began having pain in the lower right quadrant of the abdomen. I saw her that evening about 9:30 in one of the local hospitals. She was acutely ill and lay with her legs flexed. Her temperature was 104 F, pulse 120 and respiration rate 26. The blood pressure was 120 systolic 76 diastolic. Complete examination revealed moderate voluntary rigidity of the lower right rectus muscle and tenderness in the right lower quadrant most marked over McBurney's point. There was tenderness over the right femoral ring which was localized and more pronounced than the abdominal tenderness. On the anteromedial aspect of the lower third of the right leg there was an area of moderate tenderness 4 cm in diameter in which there was yellowish green discoloration. There was no swelling. The white blood count on admission was 23,300 with 88 polymorphonuclears. The urine showed albumin one plus and from 4 to 6 white cells per high power field. Aside from the usual childhood diseases and a secondary anemia for which she was treated some five years before the patient had been in excellent health. The family history was irrelevant. Red blood cells numbered 4,500,000 and hemoglobin was 85 per cent on admission. I saw the patient again the following morning at which time the condition was about the same as on the preceding night. The fever had persisted throughout the night but there had been no further chills or vomiting. The physical examination revealed the same condition. The leukocyte count was 19,800 with 80 per cent polymorphonuclears. The urine showed many pus cells but no clumps. The patient stated that about ten days prior to the onset of the present illness she had dropped a wooden grocery box on her right shin but paid no particular attention to the injury at that time. The following day it was black and blue at the site of the bruise but she disregarded it. Because of the persistence of the abdominal pain, fever and leukocytosis an exploratory laparotomy was performed that afternoon. No pathologic changes were noted and a normal looking appendix was removed. The microscopic report was chronic appendicitis. The morning after the operation the temperature and pulse were still elevated and the area of tenderness over the femoral ring was still present and pronounced. That afternoon the right foot and ankle became swollen, red and painful. This swelling gradually subsided and convalescence was further uncomplicated. She left the hospital on the twelfth day. When she began to walk the swelling of the right leg returned and has persisted until now, some ten months after the operation in spite of the use of a support and of heat and massage therapy. Please omit name. M D Iowa

ANSWER—Ten days after an injury to the leg with ecchymosis, the sudden onset of chills, fever of 104 and a high leukocytosis with tenderness over the site of the injured leg, the femoral ring and the iliac fossa should suggest an acute thrombophlebitis.

It is unusual for an appendicitis to begin with a chill but the conditions found should have been sufficient to make a clinical diagnosis rather than resort to an exploratory laparotomy.

The persistence of swelling of the leg indicates that the deep femoral vein and probably the external iliac were involved, although acute inflammation of the femoral and pelvic lymph glands might have caused the tenderness over the groin and the iliac fossa.

Continued bandaging of the leg is indicated as it will relieve the swelling and permit collateral circulation to develop. It should be used as long as the swelling increases on standing.

CARCINOMA OF COLON

To the Editor—A man aged 79 gives a history of abdominal cramps with constipation alternating with explosive diarrhea. A barium sulfate enema revealed an obstruction at the junction of the sigmoid colon and descending colon. The symptoms are of about five months duration. The patient's general condition is good for his age. The blood pressure is 140 systolic 90 diastolic and the pulse rate is 76. An exploratory laparotomy revealed a large mass at the area of the colon mentioned which was considered irremovable because of its being matted down and because of its being inflamed and almost ready to perforate. The operator palpated the liver and felt no metastatic nodules. The patient progressed well after the operation and the colostomy which was performed at the operation functioned satisfactorily but he still complains of cramplike pains over the area of the mass which require the administration of opiates. Please discuss the efficacy of x-ray treatments in such a case or the use of radium seeds through the colostomy into the mass. Are the reactions to the use of x-rays or radium quite severe? If there are no reactions would such treatments relieve pain? What is the prognosis in such a case as to comfort until the carcinoma proves fatal? If published please omit name. M D New York

ANSWER—Radium seeds are distinctly contraindicated in this case for numerous reasons, but primarily because of the extent of the lesion. X-rays and radium have generally not proved successful in the cure of cancer of the colon. Under certain conditions these agents have relieved pain. By a proper technique reactions can be minimized and sometimes entirely avoided. Whether or not roentgen treatment should be used in this particular case is an individual decision which must be governed largely by the general condition of the patient. In view of his age one should be careful to maintain and not influence adversely his general condition. Since cure is practically out of the question only palliation can be expected. If it is decided to try irradiation as a palliative measure, the dose must be small and the fields not too large. Treatment should be continued only in the face of improvement and promptly discontinued if the general condition of the patient becomes worse. In general, treatment under these conditions, even as a palliative measure, is questionable.

TREATMENT OF PRURITUS VULVAE

To the Editor—A woman aged 60 first came to me with arthritis of the thumbs which has improved with a dietary regimen and active ray treatment. She also complained of pruritus vulvae. Pelvic examination showed a reddened mucous membrane and some abraded areas. The outer portion of the right labium majus had a follicular papular eruption. The uterus was small and retroflexed. The vaginal secretion was very acid, small in amount and negative for *Trichomonas vaginalis*. The urine was negative. Local application of zinc oxide ointment and douches of sodium bicarbonate and aluminum acetate and occasional ultraviolet irradiation improved the condition for a while. Then the condition became worse and I used theelin in oil December 4, 7 and 10. The condition grew much worse with both labia majora half covered with follicular papules, the mucous membrane reddened and raw. Theelin was discontinued. The patient is now taking douches. I painted the mucous membrane with 10 per cent silver nitrate and used Mennen's Baby Oil on the labia. The ointment dried and irritated on removal. The patient's arthritis has improved and her general condition is good but she is nervous and this vulvar condition makes her more so. She is taking phenobarbital now and promises to stay in bed for several days. Is there any suggestion? Is roentgen irradiation the only other possibility? Please omit name. M D Ohio

ANSWER—A small amount of secretion such as is stated to be present in this case, is seldom highly irritating except in the presence of obstructed drainage. The first thing to be determined is whether there is a blockage of the cervical canal predisposing to retained secretion. If this is present, relief of the obstruction may effect a cure.

Employment of contraceptive medicaments, the use of inadequately lubricated or irritating condoms, or too hot or too cold or too strong douche solutions may be factors in the irritation.

Despite the absence of trichomonads on a single examination they may be present. Other causes of high grade inflammation, such as yeast infection or a virulent pure growth of a specific organism, should be looked for in wet preparations, in stained smears, and perhaps in cultures.

Failure to ascertain a specific cause of the trouble either systemic such as diabetes, or local, as suggested, impels one to turn to nonspecific care. Vaginal instillation of 3 per cent tannic acid in glycerin 3 cc instilled nightly with the hips elevated, tends to keep the parts dry and alleviates inflammation. In severe cases the tannic acid-glycerin mixture may be used twice daily.

Kaolin ointment is superior to all other ointments in genital rawness and irritation, such as this.

The parts should be kept dry, washed little and doused as little as possible. Open air treatment, with sunlight lamp therapy once or twice daily for a half hour or more is helpful.

Even in the certain absence of diabetes, a blood sugar determination should be made. Whether normal or too high, a reduction of carbohydrates in the food promotes healing of stubborn vaginal inflammations and infections.

The present discussion presupposes not only a careful routine examination of the genital tract but repeated examinations in search for a pathologic condition that may have been overlooked. In this study the services of an internist and local examination by a dermatologist should be utilized. Many vulval lesions that are baffling to the gynecologist are promptly recognized and quickly cured by a dermatologist.

HERNIA IN INDUSTRIAL WORKER

To the Editor—A man aged 65 in fair general health has a hernia that has never produced symptoms is easily reducible but comes out readily when standing and is about the size of a marble (three-fourths inch or 2 cm). He absolutely refuses operation and has been given a light job. Should he also be made to wear a truss (the downward extension attached to a spring truss frame)? One group here says yes but the other holds that (1) all a truss can possibly do is to prevent the hernia coming out of the saphenous opening (2) it rarely even accomplishes this if the man is active, (3) it is a definite source of danger in that by constant irritation over the femoral canal adhesions may be produced and the hernia rendered irreducible and (4) strangulation almost never occurs at the saphenous opening but over the sharp edge of Gimbernat's ligament and is almost as likely to occur with a truss as without. Please omit name.

M D New York

ANSWER—In a femoral hernia, operation should be recommended unless contraindications exist, when a truss should be advised if it can be properly fitted. In some instances a truss will be satisfactory, in others it may permit light or clerical work, while in a few instances, usually owing to a large hernia or to improper fitting, it may be not only useless but harmful.

Since many persons with a femoral hernia do their ordinary work for years without distress or strangulation, one must conclude that while operative or mechanical treatment is advisable it is not absolutely vital.

Operative treatment as often performed through the saphenous opening frequently results in a recurrence and while the inguinal approach is satisfactory it requires considerable surgical experience neither being entirely free from a variety of serious complications.

After the onset of incarceration or strangulation, if the operation is performed early the risk should not be increased to any extent. Practically the mortality is considerably higher, because of late diagnosis and operation.

Since no treatment can be called entirely free from danger or recurrence of the hernia, the patient should be informed and given a voice in the decision. Precautions in work may minimize the dangers of strangulation or the disadvantages of a truss.

Since a femoral hernia is a potential hazard, it should be within the province of the employer to make certain rules giving the physician familiar with the physical condition and occupation of the individual and with the local surgical practice a certain flexibility in enforcement.

While it is possible to outline certain principles and based on them make basic rules the first consideration of which should be the welfare of the individual or groups of individuals, their application may vary in different communities but as a general policy the individual should be permitted the final decision.

THE END REACTION OF PRUNES IN THE BODY

To the Editor—Are prunes acid in their end reaction?

M D California

ANSWER—A short general classification of foods into those which yield a neutral ash, an acid ash or an alkaline ash was provided in the discussion on acid ash foods and salty taste in the mouth (THE JOURNAL, April 3, p 1200).

The potential alkalinity of dried prunes as calculated by the method of Sherman appears to be about 270 cc of tenth-normal alkali per hundred grams of the edible portion. It was pointed out by N R Blatherwick years ago, however (*Arch Int Med* 14 409 [Sept] 1914), that the eating of prunes causes an increase in the excretion of acid in the urine and a decrease in the urinary pH . Blatherwick and Long repeated the work (*J Biol Chem* 57 815 [Oct] 1923) with the same results. They found that the increased acidity of the urine was caused by the excretion of organic acids which are present in the prune and which cannot be oxidized to carbon dioxide and water by the body. These acids are benzoic acid and other compounds such as quinic acid, which yields benzoic acid in the body.

Mrah, Smith Fessler, Lambert and Harper (*J Nutrition* 8 633 [Dec] 1934) confirmed earlier observations regarding

the increase in the organic acids in the urine following the ingestion of prunes. Human subjects were placed on a neutral diet, and the eating of from twelve to eighteen prunes caused an increase in organic acids, a decrease in ammonia and total acids and an increase in the hydrogen ion concentration of the urine. The carbon dioxide-combining power of the plasma was not changed significantly when prunes were eaten, an observation which might be expected in view of the fact that the blood tends to maintain a constant composition, as shown by Bischoff, Sansum, Long and Dewar (*J Nutrition* 7 51 [Jan] 1934) and others.

Prunes, therefore, should be thought of as a food the ingestion of which tends to make the urine more acid but which has no effect on the alkaline reserve of the body.

CALCIUM LEVELS IN JAKE PARALYSIS

To the Editor—A man aged 31 a research worker whose duties entail the frequent handling of ortho meta and para cresol phosphate, has come to me for care. He complains of soreness over his entire body particularly marked over the tips of the shoulders. There is some slight pain on beginning joint motion which subsides but does not disappear completely with activity. The general physical examination is negative. There are no joint signs no true paralyses and no signs of focal infections. His fasting blood calcium on the two occasions tested was respectively 14.7 and 14.4 mg. His blood phosphorus is 4.4 mg. The blood count shows no peculiarities of blood cells but a very moderate anemia of secondary type. The urine is negative for sugar and albumin. Have any studies been done on the calcium levels in jake paralysis? Tricresol phosphate, as you remember, is the active substance in those paralyses. Please omit name.

M D, New York

ANSWER—A thorough study of jamaica ginger paralysis, or "jake" paralysis, has been made by the National Institute of Health of the U S Public Health Service. The final conclusions on the etiology of this kind of paralysis were given in a second report by Smith, Elvove and Frazier (*Pub Health Rep* 45 2509 [Oct 17] 1930). The following quotation from the 1930 Year Book of Nervous and Mental Diseases refers to the query: "A pharmacologic study of the action of phosphoric acid esters of phenol and some of the cresols has shown conclusively that triortho cresyl phosphate, and in so far as the present evidence goes, it alone, can produce in experimental animals a specific type of motor paralysis of the extremities in every sense comparable with that which occurred recently in human victims who drank of an adulterated fluid extract of jamaica ginger." In this study and in a preliminary report by the same authors (*Pub Health Rep* 45 1703 [July 25] 1930) will be found the results of phosphorus determinations in "jake" paralysis. It is difficult to explain a high calcium level in association with a rather high phosphorus level as reported in the correspondent's case.

PULSE VOLUME IN CERVICAL RIB

To the Editor—I am writing to ask you to settle a dispute which has arisen between some men in our suite on the subject of cervical rib. The argument centers on the fate of the pulse when the arm on the affected side is raised or lowered. Textbooks give contradictory answers, Homan's Surgery leading the reader to believe that the diminution of pulse volume is greatest when the arm hangs by the side and Meakin's textbook on internal medicine giving the opposite view. Your opinion on the question would be appreciated. Kindly omit name.

M D Illinois

ANSWER—In the majority of cases of cervical rib, the radial pulse is entirely unaffected. Less than 10 per cent of cervical ribs cause symptoms of any kind and only a fraction of this 10 per cent produce changes in pulse volume. Consequently, as a diagnostic point indicating the presence of cervical rib, change in pulse volume is of no great significance because of its infrequent occurrence.

In almost all cases in which the pulse is affected, it is found to be diminished when the shoulder girdle is lowered and the arm is hanging by the side. This occurs not because of direct pressure by the rib on the subclavian artery but because of elevation and displacement of the scalene muscles. This displacement causes a stretching upward of the subclavian arch. Lowering the shoulder girdle causes a pull against the elevated subclavian artery with a consequent diminution of the radial pulse volume.

In rare instances the accessory rib extends around to unite with the first rib near the sternum. In these rare instances elevation of the arm may compress the artery against the under surface of the accessory rib and thus cause a diminution of the pulse volume in the elevated arm. It is in such cases that thrombosis of the artery is likely to occur because it is subjected to trauma with any arm movement. Fortunately, such cases are exceedingly uncommon.

EFFECT OF FALL ON PELVIC ORGANS

To the Editor—A woman previously well was injured in the act of sitting down when the chair tipped and she fell to the floor in a squatting position. At the time of her accident she felt severe pain in the back, the pelvis and both inguinal regions. Roentgenograms of the back taken shortly after the fall disclosed no spinal injury. No pelvic examination was done at that time. Afterward she complained of pain in the lumbar region, a feeling of heaviness in the pelvis, constipation and urinary frequency. Nine months later examination of the heart and lungs gave negative results, the blood pressure was 125 systolic and 80 diastolic, the hemoglobin content was 70 per cent and there were pus cells in the urine. On pelvic examination rectocele, cystocele and prolapse of the uterus were observed. The previous medical history is irrelevant. An appendectomy and an oophorectomy and salpingectomy on the right side had been performed fifteen years previously. Since the patient was perfectly well prior to the fall could the injury at the time of the fall have caused her rectocele, cystocele and prolapse or have aggravated a previously asymptomatic condition? M D New York

ANSWER—A fall to the floor could not produce rectocele or cystocele, at the most it could be a precipitating cause of these lesions if they were about to develop. A jolting fall, notably on the sacrum, sometimes causes retrodisplacement of the uterus in an apparently healthy patient. It is doubtful that prolapse of the uterus would result from a similar fall. Any lesion may become symptomatic after an injury.

PATHOLOGY OF THE APPENDIX

To the Editor—At a recent staff conference the attending pathologist smilingly asserted that he never found a normal condition in any specimen removed from the abdomen. Does this violate the code of ethics? It seems to me grossly immoral. I would be interested to know how the American Medical Association regards a statement like this. Is there any way to differentiate the dilatation of vessels in the appendix due to inflammation and merely clamping the base of the appendix? Please omit name. M D New York

ANSWER—The statement of the pathologist does not violate the code of ethics if it reflects correctly his experience in the examination of specimens removed from the abdomen. The essential difference between dilatation of the vessels of the appendix from clamping the base and from inflammation is that in the latter case there are present also exudation and leukocytic emigration. In the earliest stages of inflammation, microscopic examination may be necessary to determine the true nature of the process.

INTRAMUSCULAR INJECTION IN BUTTOCK

To the Editor—With regard to your reply to my query of Oct 4 1936 regarding intramuscular injection into the buttock I feel that your directions are not sufficiently exact to be useful. You say "Divide the buttock into four quadrants." My point is that one must outline an area before one can divide it. I should like to have you give me the exact anatomic outline of the buttock from which you arrange it into four quadrants. Trusting you will bear with me in persisting in this. Please omit name. M D Washington

ANSWER—The doctor may drop a line horizontally on his patient from the midline of the crest of the ilium. Another line should be drawn transversely to this at just above the insertion of the coccyx into the sacrum and running across to just about the insertion of the head of the femur into the acetabulum of the hip bone. The injection should be given into the upper and outer quadrant formed by these two lines. The physician so interested might look up Shaffer, L W. The Fate of Intragluteal Injections, *Arch Dermat & Syph* 19 347 (Feb) 1929. The entire anatomy and technic is well illustrated.

EVIDENCE OF LEAD POISONING

To the Editor—Does the presence of 12 mg of lead per liter of urine constitute evidence of lead poisoning? A man aged 47 is in the printing business but not connected with type setting. For six months he has had a mild neuritis of the peroneal nerves more marked on the right side. In my own library I cannot find requisite data. Your help would be much appreciated. Please omit name. M D Maine

ANSWER—One of the most difficult tests that clinical laboratories are called on to make is the quantitative determination of lead in the urine. Some high type of clinical laboratories, as found in hospitals and elsewhere, turn out flagrantly erroneous results of urinary lead determination. Though this report of 12 mg per liter of lead in the urine is by no means condemned as inaccurate, the suggestion is made that a conclusion should not be drawn from one single quantitative test but from a series of several. Most normal persons without demonstrable exposure to lead excrete lead in the urine in quantities on the order of 0.1 mg per liter. So high a figure as 12 mg per liter is out of the normal range and strongly suggests the possibility of lead poisoning, provided always the test has been accurately made. Reference should be made to a publication by

Kehoe, Thamann and Cholak entitled "On the Normal Absorption and Excretion of Lead" (*J Indust Hyg* 15 257 [Sept] 1933) and a somewhat similar article by the same authors in the same journal (18 42 [Jan] 1936).

VITAMIN B₁ IN HERPES ZOSTER

To the Editor—I have noticed that vitamin B₁ is giving excellent results in many cases of polyneuritis, fascial neuralgia and similar conditions. Can you give me any information as to the value of vitamin B₁ in old people with severe neuritic pains occurring years after an attack of herpes zoster? J M MEYERS M D, Superior Wis

ANSWER—In a recent paper by Martin G Vorhaus on the present evaluation of vitamin B₁ therapy (*Am J Digest Dis & Nutrition* 3 915 [Feb] 1937), mention is made of the value of vitamin B₁ in the treatment of postherpetic neuritic pains. Attention is directed to the clinical observation that modification of the postherpetic paresthesia and anesthesia occurs following large doses of vitamin B₁ in comparison to a control group of cases without vitamin therapy.

It is recommended that vitamin B₁, either natural or synthetic, be administered orally in doses of 2000 international units daily. The duration of treatment depends on the severity of the attack and the length of time elapsed since the attack. In mild or moderate cases of herpes zoster, modification of the postherpetic sequelae is often noted in from three to four weeks. In severe cases, and in those cases in which the postherpetic pains have lasted for three months or more, treatment should be continued for eight weeks or longer.

The response to vitamin B₁ therapy depends, apparently, on the state of the peripheral nerves involved. When complete destruction of these nerves has occurred, no response can be expected. When only partial destruction seems to have taken place, improvement in the symptom may be noted.

PROTECTION OF HANDS FROM INDUSTRIAL IRRITANTS

To the Editor—A patient working with Sol Kleen an 'acid' to remove grease from metal cannot use rubber gloves because he also uses pyroxylin solution, which seems to dissolve rubber. His hands crack badly. He cannot use petrolatum on them for he gets it on the metal. What do you suggest? D C ANSTUTZ, M D, Bellefontaine Ohio

ANSWER—It is by no means necessary to use acids as degreasing agents in industry, nor is it essential that the hands of workers come in direct contact with metal parts in the process of degreasing. One of the most salutary features of automatic industrial processes is that often the worker is removed from close proximity to injurious agents. At present, much polishing and buffing is carried out under conditions preventing any close proximity between the worker and the dusty operations. Degreasing may also be carried out automatically. A pharmaceutical manufacturer has introduced a protective agent for the skin of industrial workers called Tar Dermament. It is said to be greaseless and thus to obviate the difficulties growing out of the use of greasy protective agents. Final proof of the efficacy of this new agent is lacking, but its judicious use seems to be warranted.

CALCIUM IN EGG SHELLS

To the Editor—1 What is the chemical combination of calcium in the egg shell? 2 How effective is powdered egg shell as a means of therapeutic calcium administration? M D West Virginia

ANSWER—1 The calcium of the egg shell is almost entirely in the form of calcium carbonate. The shell of the average sized egg contains approximately 5 Gm of this salt.

2 Calcium carbonate, which makes up more than 90 per cent of the egg shell, is in an easily utilizable form and appears to be absorbed as well as the water-soluble chloride, lactate or acetate, which is generally prescribed.

USE OF BLOOD SERUM OF THYROIDECTOMIZED GOATS IN HYPERTHYROIDISM

To the Editor—Will you kindly comment on the value of blood serum of goats deprived of the thyroid gland in treating hyperthyroidism. I have at hand some literature on this subject received from a drug house which obtains this material from the Instituto Sieroterapico Milanese. Please omit name. M D Rhode Island

ANSWER—Some years ago, use of milk from thyroidectomized goats and also the serum from thyroidectomized goats was advocated in various places abroad and here. There has been no evidence, however, that it has any value and there is no reason to believe that it deserves anything but the oblivion attached to it.

Council on Medical Education and Hospitals

ADDITIONAL HOSPITALS APPROVED

The Council on Medical Education and Hospitals of the American Medical Association has given its approval to the following hospitals since the publication of the last previous list in THE JOURNAL, March 13, 1937

Hospitals Approved for Intern Training

Hospital of St Raphael New Haven Conn
Cook County Hospital Chicago
W A Foote Memorial Hospital Jackson Mich
Mercy Hospital Jackson Mich
Buffalo Hospital of the Sisters of Charity Buffalo
Beekman Street Hospital New York City
Crouse Irving Hospital Syracuse N Y

Hospitals Approved for Residencies in Specialties

St Vincent's Hospital Birmingham Ala Mixed
Cook County Hospital Chicago Radiology
Sanatorium Division of the Boston City Hospital Boston Tuberculosis
Cambridge Hospital Cambridge Mass Surgery
Foxboro State Hospital Foxboro Mass Neuropsychiatry
North Reading State Sanatorium, North Wilmington Mass Tuberculosis

Book Notices

Safe Driving Human Limitations in Automobile Driving By J R Hamilton and Louis L Thurstone M E I D Boards Price \$1 Pp 74 with 6 Illustrations Carden City New York Doubleday Doran & Company Inc 1937

In this book a psychologist and an advertising man have collaborated to present a study of the factors involved in driving, with a view to determining the causes of accidents and to make recommendations for their prevention. Sixty per cent of all the accidents occur on the highways 40 per cent in traffic lanes. The authors insist that most accidents are the result of human limitations. On the highway, most accidents occur through the driver's ignorance of human vision. In traffic lanes the accidents are the result of delayed responses. The analysis of the relationship of vision to accidents is convincing. When a person is driving at the rate of from 40 to 45 miles an hour the only point at which he gets a clear picture of the foreground is about 80 feet ahead of the car. At 50 miles an hour ruts and breaks in the road are not seen clearly. At 60 miles an hour the foreground is not seen at all. Moreover a last minute glance at trouble does not help because the speed is too great to permit any action. Certainly the importance of good vision for safe driving cannot be overestimated. The analysis of difficulty in traffic lanes is similarly scientific. The limitations of the human being on foot and the limitations of distance at which the life of that human being is in the driver's hands can be measured at any given speed. Even when the pedestrian is 107 feet in front of the moving car, his life is in danger from the driver of that car. The authors conclude that safety for the good driver lies between 40 and 50 miles an hour. Below 40 miles an hour he is not safe against other drivers. In traffic lanes, where driving is more complicated, conditions change. An unprotected intersection should not be crossed at even 20 miles an hour without the foot on the brake. This book lays down a series of yardsticks for drivers and pedestrians which authorities cannot afford to neglect.

On Deficiency of A Vitamin and Visual Dysaptation By C Edmund and Sr Clemmesen Paper Price 5 Danish kroner Pp 92 with Illustrations Copenhagen Levin & Munksgaard London Oxford University Press 1936

The recent progress in the chemical identification of vitamins has brought about a demand for the clinical demonstration of early deficiency states. This has been particularly true for vitamin A. The classic deficiency state of xerophthalmia is seldom seen even in large clinics in this country. Some years ago it was shown that the power of distinguishing variations of light in persons suffering from lack of vitamin A was inferior to the power in individuals on a normal diet. Early investigations were concerned with the determinations of the sensibility of the eye to light of different intensity by measuring the minimum visible. This demonstrated faulty adjustment to darkness and improvement with administration of vitamin A. Later photometric tests were devised. This monograph takes up the historical development of this approach and gives a critical evaluation of the various methods employed. The authors present in detail the method they have employed in the investi-

gation. It is essentially a modification of the technic of Moller and Edmund. The authors do not employ wing lamps for illumination but a single globular electric alabaster glass Osram bulb placed at a certain distance from a concave mirror so that the plate of types is diffusely illuminated. Detail of method and sources of error are given in detail. Normal values are presented together with seasonal oscillations in Denmark which were greater in spring and fall, changes due to age and maximum and minimum fluctuations. The experimental data were concerned with the study of pregnant women who were suspected of A deficiency due to vomiting, liver disease or other pathologic conditions and normal subjects of various types. Of forty-nine pregnant patients examined, twenty-four showed a pathologic decrease of their power of distinction. The authors prefer calling the disease dysaptatis instead of hemeralopia. Three of these had the defect in spite of a previous ample supply of vitamin A by mouth. Intramuscular injection of vitamin A brought about prompt disappearance of the dysaptatis. The recurrence of dysaptatis after recovery by parenteral injection of vitamin A made the authors believe that the resorption of vitamin A absorption from the intestinal tract is reduced in pregnant women. Protocols of the various experimental groups and controls are presented in detail. The work is strictly not a monograph on the subject but a detailed presentation of an experimental investigation of rather limited scope. It should interest the ophthalmologist and obstetrician, particularly if the results are confirmed.

Recent Advances in Orthopaedic Surgery By B H Burns BA B Ch FRCS Orthopaedic Surgeon to St George's Hospital and V H Ellis MA B Ch FRCS Orthopaedic Surgeon to St Mary's Hospital London Cloth Price \$5 Pp 296 with 108 Illustrations Philadelphia P Blakiston's Son & Co Inc 1937

In line with the policy of the "Recent Advances" series, the authors have attempted to discuss the present status of orthopedics in the light of newer developments. The subject matter is judiciously presented and generally expresses the consensus. On controversial problems, the various theories are presented concisely and fairly. The opening chapters, on bone growth, transplantation and chemistry, present an elemental but fundamentally sound review. Tumors of the bone are treated in compendium, almost outline, fashion the classification of Geschickter and Copeland being followed. Osteomyelitis, arthritis and suppurative arthritis are discussed briefly. The section on tuberculosis of the joints is conservative. However, the recommendation of the authors to allow patients to walk in a knee length spica for from six to eight weeks, preparatory to a fusion operation on a tuberculous hip that has just become quiescent, may be questioned. The dangers of recrudescence outweigh the benefits of improved circulation and muscle tone. Furthermore, pyogenic superinfection, through a sinus tract is considered a calamity. It is now believed that such infection may favor sclerosis and healing. One is also inclined to disagree with the statement that "occasionally areas of increased density may be observed in the subchondral bone, and are probably due to filling of marrow space by tubercles and granulation tissue." Such areas would appear less dense in the roentgenogram. Congenital dislocation of the hip is discussed from the standpoint of the Lorenz treatment, Putti abduction in infants, open reduction, shelf operations and osteotomies. The recumbency-traction treatment of Perthes' disease is sound. The authors stress the efficacy of simple traction in abduction and internal rotation in the treatment of adolescent coxa vara (slipped epiphysis). Internal derangements of the knee joint are discussed competently. The descriptions of lesions of the external cartilage, including discoid cartilage, and of MacMurray's sign for the diagnosis of posterior tear of the internal cartilage are worth noting. Painful shoulders" represents a meaty, well organized summary of Codman's work. Disorders of the spine and pain in the lower part of the back are treated intelligently. Bankart's technic of manipulation for sacro-iliac and chronic lumbar strain is stressed. The indications for conservative and surgical treatment of Pott's paraplegia as described are sound. The authors stress the preoperative diagnosis of anterior poliomyelitis and favor the early use of convalescent serum. The operative treatment of stenosing

tendovaginitis, trigger finger and snap thumb is mentioned. One agrees with the statement that the flat foot is not necessarily a painful foot. Lambinudi's operation in cases of pes cavus (tenotomy of the toe extensors and immobilization in extension on a special foot plate) is offered as a substitute for or adjunct to Steindler's plantar stripping. Clubfoot is mentioned briefly, the authors prefer management by manipulation and immobilization in a special splint, as advocated by Denis Browne. The illustrations throughout the book are excellent. Faulty proofreading, however, has left many errors in spelling, sentence structure and grammar in the text.

Les hemorrhagies utérines avant et après la ménopause. Par Claude Bécclere. Préface du Dr Jean Quénu. Papier. Price 50 francs. Pp 209 with 68 illustrations. Paris: Masson & Cie 1936.

This book is divided into three parts. In the first the author deals with the physiology of normal and abnormal uterine hemorrhages and the physiology of the menopause, in the second he takes up abnormal uterine hemorrhages before the change of life and in the third section he discusses abnormal uterine hemorrhages after the climacterium. The author is of the opinion that when the menses have ceased for one year the menopause has already set in. In cases of doubt, hot flashes set the definite time of appearance of the menopause. The hemorrhages that occur before the climacterium are the most frequent ones. Among every hundred women who have hemorrhages between the age of 40 and the completion of the menopause, only thirty have objective lesions which require surgical intervention. In the remaining seventy the bleeding is functional and these women respond only to medical or roentgenologic therapy but not to surgical treatment. Among the thirty women who require surgery, eight have cancer of the body of the uterus. This can readily be determined by curettage or hystero-graphy. Among the seventy cases of functional bleeding under 45 years of age, treatment should be medical, but in those beyond this age, the treatment of choice is roentgen therapy. In the opinion of the author, carcinoma of the body of the uterus in cases of postmenopausal bleeding is not as frequent as is usually believed. He found an incidence of only 40 to 50 per cent in his cases. The other causes of postmenopausal bleeding are senile metritis, polyps and other benign changes in the uterine mucosa. The author reserves hysterectomy for cases of cancer of the uterus and he prefers the abdominal route. The book is based on the author's experience in more than 150 personal cases. It is clearly written and abundantly illustrated. The illustrations include a large number of hystero-graphs because the author is an enthusiast of this diagnostic procedure and relies on it to make the diagnosis of cancer of the body of the uterus. The book does not contain anything new but it is an excellent exposition of the subject of menopausal hemorrhages.

Clinical Roentgenology of the Cardiovascular System. Anatomy—Physiology—Pathology—Experiments and Clinical Applications. By Hugo Roessler, M.D. Associate Professor of Roentgenology and Cardiologist, Department of Medicine, Temple University School of Medicine, Philadelphia. Cloth. Price \$7.50. Pp 343 with 199 illustrations. Springfield, Illinois & Baltimore: Charles C Thomas 1937.

This book presents the application of roentgenologic methods to the diagnosis of disease of the heart and blood vessels. The subject is opened with a discussion of roentgenologic technique and a consideration of the normal anatomy and measurements and the dynamics of the cardiovascular system. Here also are considered the changes brought about by certain physiologic causes, such as exercise and pregnancy, and the changes brought about by a few pharmacologic agents. The remainder of the book, about two thirds of it, is given over to a discussion of cardiovascular disease. The x-ray appearances in disease are taken up, first from an etiologic standpoint and secondly as to the structural changes. Disease of the aorta and the pulmonary arteries is discussed. Pericardial disease is carefully considered, as is also peripheral vascular disease. There is a short chapter on disturbances of rate and rhythm and one dealing with congenital heart disease. So great is the enthusiasm of the author that it is difficult to remember that only an aid to diagnosis in cardiovascular disease is involved. The pages on kymography and densitometry will prove a bit difficult for the clinician, and the portion of the book dealing with measurement

contains numerous mathematical formulas that are most complex. This part of the book, however, will doubtless interest the roentgenologist. One wonders a little about the author's selection of material. Surely the x-rays are of no great value in the diagnosis of anemia, polycythemia and starvation. He occasionally gets a bit off the beaten track when he discusses the pharmacologic action of drugs. In dealing with pure roentgenology, however, he is on thoroughly familiar ground, so familiar that it seems doubtful that such work as he describes could be carried out in many x-ray laboratories. Such an understanding of roentgenology would greatly lighten the burden of the clinician. The book is profusely furnished with excellent illustrations, and the bibliography is tremendous, although the author mentions its incompleteness.

Occupational Hazards and the Painter with Special Reference to New York. By Adolph B. Gersh. Paper. Pp 99 with 26 illustrations. New York: Brotherhood of Painters, Decorators and Paperhangers of America. District Council No 9 1937.

It is encouraging that labor unions themselves are displaying interest in organized efforts for the prevention of accidents and occupational diseases. This brochure, apparently prepared by a layman, presents the hazards in the work of the house painter and the painter's attitude toward them. There are five chapters, dealing with the evolution of the painting trade, the causes of accidents, occupational diseases, the cost of industrial hazards, and administrative problems. Many challenging facts are presented, but exaggeration appears too often. Resort is had to overemphasis when the bald statement of established truths would have carried greater conviction. In chapter 1, for example, mention is made of an alarming increase in cases of chronic benzene poisoning, but in another chapter it is stated that the use of benzene has decreased. As a matter of statistical record, much less benzene is now used as a constituent of paints than in previous years, and it is equally well established that the number of cases of benzene poisoning has definitely diminished. The net result of repeated overstatements is to attribute to house painting as a trade a quality and quantity of exposures not fully justified by the facts. As an outgrowth of activities within organized labor to procure more satisfactory working conditions, this publication may be praised. It stands as evidence of the increasing maturity of organized labor. In some respects, it indicates a state of mind similar to that in the ancient trade guilds of Europe.

Cirugía reparadora de las lesiones de los nervios periféricos. Por Abelardo Ibáñez Benavente, coronel de sanidad. Con la colaboración del Dr. Valentín Gómez, teniente coronel de sanidad. Papier. Pp 126 with 77 illustrations. La Paz, Bolivia: Casa Editora renacimiento 1936.

This is the first of a series of books on surgery of war which the authors are going to publish in the near future and in which their experience in the Chaco war is compiled. The first book deals with the surgical repair of lesions of the peripheral nerves caused by wounding of the nerve, nervous injury by wounded structures or fractured bones and operative trauma. The first five chapters in the book are given to the general study of the subject, with special reference to diagnosis and clinical evolution. The anatomopathologic lesions that the nerves suffer from the wound or by the complicating infection or sclerosis are shown by photomicrographs. Roentgenograms in cases of fractures complicating nervous lesions are also shown. The fifth chapter is given to the treatment. In general the surgical principles established in the World War were followed. Besides, the authors summarize their own principles as follows. All syndromes showing physiologic nervous discontinuation are subjected to a surgical examination. The technique for a reparative operation includes wide and deep incision at the probable seat of the nervous lesion, identification of the nerve and either repair of the nerve or neurolysis. Repair of the nerve is made by approaching the ends in apposition, removing the injured and neuromatous nerve tissues, performing three equidistant transneurlematic suture points at the nerve ends and then an end to end suture. In certain cases it is necessary to change the course followed by the nerve so as to make it shorter than the normal one. This is made by passing the largest nerve segment through an intramuscular tunnel to meet the shorter nerve segment for an end to end suture. After being repaired, the nerve is left in a bed of

muscular normal tissue protected against proximity of bone or cicatricial tissues. The treatment is complemented by physical therapy. The indications, technic and opportunity for using grafts of nervous tissues is discussed. Neurolysis can be perineural or intraneural. Regeneration of the nerves is infrequent in war lesions. A chapter is given to pain from nervous injury and its treatment. One agrees with the author that sympathectomy and reflexotherapy fail to control pain if the anatomic and physiologic continuity of the nerves is interrupted. Because of the fact that the radial and ulnar nerves are the most frequently injured in war wounds, a special technic for their surgical repair is given. Except for slight variations, the steps for the operation, management of the nerve and operative and postoperative care of the patient are almost identical to those previously described by the author in the chapter given to repair of the peripheral nerves. The intramuscular tunnel for passage of the nerve is made at the bicipital or bicipitobrachial muscles in transposing the radial nerve, and through the epitrochlear muscles in transposing the ulnar nerve. The book fulfils its purpose of being of interest for military surgeons. It is well prepared, and the illustrations showing the technic are clear and neat.

The Practitioners Library of Medicine and Surgery. Volume XI. Eye, Ear, Nose and Throat. Superintending Editor, George Blumer, M.A., M.D., David P. Smith, Clinical Professor of Medicine, Yale University School of Medicine. Associate Editors, Arthur M. Yuddkin, M.D., Clinical Professor of Ophthalmology, Yale University School of Medicine, and Paul B. MacCready, M.D., F.A.C.S., Assistant Clinical Professor of Otolaryngology, Yale University School of Medicine. Cloth. Price \$10. Pp. 1153 with illustrations. New York & London: D. Appleton Century Company Incorporated, 1937.

This textbook is directed primarily to the general practitioner rather than to the specialist. Nevertheless, it discusses such matters as the use of the slit lamp in ophthalmology and many other technical subjects. The authors are specialists of repute in the fields on which they write. The general practitioner is frequently called on to diagnose and treat easily apparent conditions affecting the conjunctiva and the eyelids. He will be greatly helped by the excellent illustrations and the practical methods of treatment included in the discussions of these subjects. It is equally important for him to have some knowledge of various operative procedures involving the eye, although it is doubtful whether the descriptions and illustrations of technic that are supplied in this book will be of much service to him in his work. There are certainly few, if any, general practitioners who would undertake the surgical procedure in glaucoma. They should probably be much more familiar with refraction than the amount of space given to this subject. Moreover, much more space might well have been assigned to the ocular manifestations of various neurologic and internal disorders. The material on otitis media is of the greatest importance, but here again an extraordinary amount of space has been assigned to gross and histologic illustrations that can be of little real value to the general reader. The practical material on the diagnosis and treatment of the condition is excellent. This volume helps to make complete the system of which it is a part.

The Ocular Fundus in Diagnosis and Treatment. By Donald T. Atkinson, M.D., F.A.C.S., Consulting Ophthalmologist to the Santa Rosa Infirmary and the W.K. Hospital, San Antonio, Texas. Cloth. Price \$10. Pp. 259 with 106 illustrations. Philadelphia: Lea & Febiger, 1937.

The author has found it "necessary to make the text in this volume as condensed as possible" in order to keep the book small. He has made schematized black and white drawings of the various conditions of the fundus and also colored plates to illustrate the reports of cases which have seemed to him to be of interest to the physician in other specialties. The statement in the preface that many references are made in the text is not confirmed. Not a few of those found are incorrect, and there is no bibliography. The text makes easy reading because of its simple form but inaccuracies and exaggerated statements vie with antiquated terminology in bringing to the reader a distorted picture of the intended description. On page 24 is found the statement "scotomata may be due to disease of the brain or the choroid." The terms "diabetic retinitis" and "albuminuric retinitis" are used with no reference to the fact that other nomenclature is preferred. The chapter on

treatment of atrophy of the optic nerve makes no mention of the use of newer methods found efficacious in some cases. The author's diligence in producing his own illustrations in great numbers is certainly commendable. The schematic nature of the black and white illustrations and also of the colored prints, however, is not conducive to a true picture of the ophthalmoscopic appearances.

Serpents in Symbolism, Art and Medicine. The Babylonian Caduceus and Aesculapius Club. By Edwin S. Potter, M.D., Cloth. Price \$3. Pp. 85 with 36 illustrations. Privately printed, Santa Barbara, California. The Author, 1937.

The serpent symbol goes back in history to the earliest times. The serpent as a medical sign has been considered variously as the symbol of wisdom, rejuvenation, longevity and convalescence. The caduceus with the two twined serpents began in Babylonia. In Rome it was used as a symbol for secret societies and became the emblem of commerce when it was carved on the prow of the ship in trade. The two sex-double snakes conveyed, of course, sexual significance. From the Babylonian days onward, the rod and serpent had a most interesting history with various mythical relationships. These the author describes accurately. The single snake on the rod goes back to serpent worship, which preceded monotheistic religion. The special symbol of healing is the rod and serpent of Aesculapius. While Aesculapius was practicing healing and leaning on a rod, a serpent came and twined itself about his staff. Another serpent then came carrying an herb, with which it brought to life the one that had been killed. Aesculapius thereafter made use of the same drug with the same effect on man. This is the legend which makes the rod and serpent of Aesculapius the emblem of healing. There are, of course, many other emblems of medicine, but the serpent is dominant above all others throughout the world, the single rod and serpent being typical of medicine and the double serpent more frequently associated with commerce and travel.

The History of the Acute Exanthemata. By J. D. Rolleston, M.A., M.D., F.R.C.P., Medical Superintendent, Western Fever Hospital, London. The Fitzpatrick Lectures for 1935-6, 1936, delivered before the Royal College of Physicians of London. Cloth. Price 7s. 6d. Pp. 114 with 10 illustrations. London: William Heinemann Ltd., 1937.

Here are included the Fitzpatrick lectures, which deal with smallpox, chickenpox, scarlet fever, measles and German measles. J. D. Rolleston writes in a most interesting manner. He has made a thorough search of the periodical literature relating to the diseases with which he was concerned and he has an adequate appreciation of the nature of medical progress. He has accepted the contribution of Drs. George and Gladys Dick, as well established. He seems to have failed, however, to realize that the Koplik spots had been adequately described previous to the excellent contribution made by Koplik on this subject. The book is illustrated with excellent plates of some of the greatest contributors to the subject.

The Behavior of Health. By Dr. N. A. Ferri. Second edition. Cloth. Price \$1. Pp. 236 with ten illustrations. Boston: Bruce Humphries Inc., 1937.

The author, in attempting to nourish his mind at the least of reason, appears to have nibbled at everything, swallowed much and digested nothing. His thesis is a nebulous idea that there is "a subtle role played by ideas through suggestion" which will some day solve all problems, from medical through economic, and many more. The reader gets nothing from the book but a jumble of words. Such ideas as it contains are the ideas of others, usually quoted in connections in which they scarcely apply. The book is not worth the time it takes to read it.

Physiology in Health and Disease. By Carl J. Wiggers, M.D., Professor of Physiology in the School of Medicine of Western Reserve University, Cleveland, Ohio. Second edition. Cloth. Price \$9. Pp. 1124 with 191 illustrations. Philadelphia: Lea & Febiger, 1937.

The first edition of this volume was published in 1935. Since that time the author has been preparing the present revision. Certain discussions have been expanded in relationship to new research in the field of physiology. Some of the original discussions have been condensed. Attempts have been made, moreover, to express in simpler language some of the more intricate and involved discussions, particularly those dealing with car-

diology, endocrinology and nerve reaction. Thus the book has been rewritten in large part, many new illustrations have been added, and the bibliography has been brought to date. The book has found for itself a definite place in a field in which many other volumes are now available and in which probably there has been more advancement in recent years than in any other of the basic sciences. Especially to be commended are the excellent printing, the outline form and the use of various sizes of type.

Tableau de la caricature médicale depuis les origines jusqu' à nos jours. Par A Weber. Préface du Professeur Laignel Lavastine. Paper. Price 25 francs. Pp 143 with 130 illustrations. Paris. E. Le François 1936.

While not at all comparable in scope to the classic book by Hollander on this subject, the Weber contribution is more modern and more adequately illustrated. At the same time it follows closely the general development of art throughout the world. The illustrations are interesting.

MEDICOLEGAL ABSTRACTS

Malpractice Categorical Answer to Lengthy Hypothetical Question Not Required of Expert Witness—A physician appeared as a witness for the plaintiff in a malpractice suit. The defendant's counsel propounded to him a lengthy hypothetical question, the framing of which began before the morning recess of the court, continued over until the noon recess and was then completed in the afternoon. The trial court required the witness, at the request of the defendant, to answer the question "yes" or "no," without qualifying explanations. A judgment of nonsuit was subsequently entered and the plaintiff appealed to the district court of appeal, second district, division 1, California, contending that the trial court erred in denying to the witness the right to explain his answer.

The record, said the district court of appeal, showed that the witness answered the hypothetical question, as to whether or not the defendant used the degree of skill and care ordinarily exercised by physicians in the vicinity, in the belief that he had to answer it with an unqualified "yes" or "no," that he understood that an affirmative answer would be an approval of all that the physician-defendant had done, an approval that he could not honestly give, and that a negative answer would be a condemnation of the defendant's entire conduct, a position that he was even more reluctant to take. He solved the dilemma in which the trial court's ruling and his understanding placed him by answering in the affirmative. The defendant cited no authority in support of the proposition that the question had to be answered categorically. In the opinion of the district court of appeal, the witness should have been permitted to explain his answer. The defendant argued, however, that no prejudice flowed from the error because the witness had effectively disqualified himself by several statements to the effect that he did not know how other physicians treated the plaintiff's condition. But, said the court, a physician with experience in diagnosing and treating a particular ailment, who has lived for thirteen years in a community, knowing and practicing with the other physicians there, may be qualified to give testimony as an expert concerning the degree of skill, care and learning ordinarily possessed by physicians practicing in the community, with respect to that ailment, although he may not have known of the ailment having been treated before in the community. If a physician, otherwise qualified, cannot measure another physician's diagnosis and treatment of a particular case by the standard of the community, because he does not know of an actual case having established that standard, it follows necessarily, the court said, that no standard of skill and care would be available on the first appearance of an ailment in a community, nor would there be any standard in a new community.

Does a physician, the court questioned, who has passed the rigid tests required before he may practice, hold himself out

to exercise no degree of skill in diagnosing or treating a case of gout because neither he nor any of his fellow physicians in the locality had ever had an actual case before? The limitation on the liability of physicians that they shall be held only to that degree of care and skill which is the standard in the community is not to be extended to relieve them of the duty of exercising any care and skill in a new situation. Physicians have been trained for new situations, the court said, and by their training and general experience have some standard to which they can be held. The judgment of nonsuit was reversed. —*McGuire v Baird (Calif)*, 62 P (2d) 184.

Harrison Narcotic Act Osteopath in New Jersey Not Entitled to Registration—The relator, Robert H. Conover, was licensed to practice osteopathy in New Jersey in 1913 under a law that defined osteopathy as follows:

A method or system of healing whereby displaced structure of the body are replaced in such manner by the hand or hands of the operator that the constituent elements of the diseased body may reassociate themselves for the cure of the disease.

In 1935 the New Jersey legislature repealed the 1913 osteopathic act and enacted a new act, which provided, in part:

Provided however that a license to practice osteopathy shall not permit the holder thereof to prescribe or administer drugs for internal use in the treatment of any human disease, pain, injury, deformity, physical or mental condition or to perform such surgical operations as require cutting.

Thereafter, Conover applied to the local collector of internal revenue for registration under the Harrison Narcotic Act and a special tax stamp was given him as evidence of registration. Later, the collector requested Conover to surrender the stamp on the ground that as an osteopath he was not qualified to use narcotics. The stamp was surrendered under protest and Conover applied to the United States district court, D. New Jersey, for an order directing the collector to show cause why a writ of mandamus should not issue to compel the reissuance of the stamp.

The 1935 osteopathic act, said the court, definitely interdicts the prescription or administration by an osteopath of any drugs for internal use in the treatment of any human disease, pain, injury, etc. Conover argued, however, that osteopaths do not administer drugs or narcotics for internal use as treatment but only for the relief of pain. The osteopathic act, however, the court pointed out, explicitly includes "pain," and the language of the act being plain and unequivocal, a strained construction is not to be applied to it.

Nor, continued the court, was the osteopathic act affected by the provisions of the Uniform Narcotic Law of New Jersey, passed in 1933, which contains the following definition:

Physician means any person authorized by law to practice medicine in this State and any other person authorized by law to treat sick and injured human beings in this State and to use narcotic drugs in connection with such treatment.

The narcotic law, said the court, cannot and does not enlarge the osteopathic act of 1935 or, in the case of Conover, the 1913 act under which he received his license to practice. If an osteopath in New Jersey is to be entitled to prescribe and administer drugs of any kind, the court said, he must obtain legislative authority to do so. Until that time, the collector of internal revenue is justified in refusing the reissuance of a "permit" to Conover. The order to show cause was therefore discharged. —*Conover v Maloney, Collector of Internal Revenue*, 16 F Supp 419.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers in continental United States and Canada for a period of three days. Periodicals are available from 1926 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Vitamins and Poliomyelitis.—Some cases of poliomyelitis that Toomey studied suggested a correlation between the lack of certain vitamins and resistance to poliomyelitis. Therefore he experimented on *Macacus rhesus* monkeys and found that the ingestion of large doses of vitamins A, B and C did not protect the animals receiving them. On the other hand, the animals that were given vitamins A, B, C and D were protected from the effect of the virus when it was introduced by way of the gastro-intestinal tract. It is paradoxical that though the lack of vitamin D makes monkeys more susceptible to poliomyelitis, the rise in the morbidity of the disease occurs at that time of year when human beings theoretically should receive plenty of the antirachitic factor from the summer sun. The author has observed recently that the blood serum of eight rachitic children taken during the active stage of the disease contained no agglutinins against organisms of the enteric group, and since the agglutinin titer against enteric organisms of blood serum taken from animals in the prostrate stage of poliomyelitis is practically nil, a possible connection is thought to exist between the lack of vitamin D and the lack of agglutinins against enteric organisms. When the roentgenographic evidence and the readings for calcium and phosphorus in the blood serum had become normal agglutinins against enteric organisms had not yet appeared, their production lagging behind

the other physical and biochemical signs of recovery. Since the lack of agglutinins against enteric organisms makes monkeys more susceptible to poliomyelitis when the virus is given by way of the gastro-intestinal tract and since this susceptibility is further enhanced by subcutaneous injections of enteric organisms and their toxins, it is not illogical to suspect a connection between the loss of agglutinins, the susceptibility to the disease and the lack of vitamin D. The virulence of virus preparations is decreased after exposure to ultraviolet radiation.

Intracutaneous Tuberculin Tests.—The basis of Law's study consisted of 732 children of low economic status who came from households distributed in towns throughout two thirds of the state of Michigan. The behavior of purified protein derivative in its two standard test doses in comparison with three dilutions of potent old tuberculin in about 3000 tests shows that the purified protein derivative is uniform in its reaction potent and reliable. The first strength of purified protein derivative (0.00002 mg) found more reactors than did old tuberculin in a dilution of 1:10,000 (0.01 mg) or about the same number of reactors as did old tuberculin in a dilution of 1:1,000 (0.1 mg). The use of the second strength of purified protein derivative (0.005 mg) found more than seven times more reactors than did the administration of old tuberculin in a dilution of 1:1,000 (0.1 mg), whereas the giving of the second strength of purified protein derivative found twice the number of reactors revealed by old tuberculin used in a dilution of 1:100 (1 mg).

Complement Fixation Reaction in Amebiasis.—Meleney and Frye are convinced that the complement fixation test in amebiasis has a practical value in detecting obscure cases of infection. A negative complement fixation reaction is of particular value in patients with chronic diarrhea or other symptoms suggestive of amebiasis, in whose stools *Endamoeba histolytica* cannot be found, and in patients formerly known to have had amebic dysentery who continue to have vague abdominal symptoms, or who fear they are not cured. In both of these groups the negative blood reaction gives reasonable assurance that amebic infection is absent. Despite their evidence that *Endamoeba histolytica* may sometimes exist in the intestine without the production of lesions every case in which this ameba is found in the stools should be treated with an amebicidal drug, both for protection of the individual and for the protection of others. A single strain of *Endamoeba histolytica* may produce no symptoms in one individual and severe amebic dysentery or abscess of the liver in another. The complement fixation test should not replace diligent search for *Endamoeba histolytica* in the stools in suspected cases. A positive complement fixation test is only presumptive or confirmatory evidence of amebic infection. Accurate diagnosis can be based only on identification of *Endamoeba histolytica* itself in the stools or in the tissues of the body.

Periapical Empyema—Kautz and Pinner state that the pathogenic factors which lead to a periapical localization remain speculative. In the acute empyemas of early childhood, pre-existing adhesions of the upper lobe play hardly a part, while it may well be the most important factor in chronic empyemas of adults. The relatively greater respiratory expansion and the greater negative pressure in the upper portions of the pleural cavity may be important. But this explanation by itself is not quite satisfactory, because if a physiologic condition were the cause of this pathologic phenomenon the latter should be frequent. That the etiologic agent is not the determining factor is clearly shown by the variety of micro-organisms that have been found both in the literature and in the authors' three cases, which are reported giving the clinical, roentgenologic, pathologic and bacteriologic observations discussed in conjunction with the few cases reported in the literature. The post-mortem changes seem to point to a more frequent occurrence of periapical pleurisy, as shown by the presence of apical pleural involvement in unsuspected cases.

Study of Low Back Pain—The striking preponderance of narrowing of the lumbosacral intervertebral disk which occurred in 256, or 57 per cent, of his cases is a significant factor to Badgley in the production of the symptom-complex. The seventy-three cases presenting normal roentgen signs, which are included in the 191 cases, or 43 per cent, with normal intervertebral joint space, present exactly the same clinical phenomena with the exception of less evidence of true neuritis as demonstrated by Achilles tendon reflex changes and sensory changes. The conclusion that superficial tenderness over the lumbosacral or sacro-iliac area is indicative of skeletal changes in the underlying joints seems to be questionable in view of the same relative frequency of this tenderness in cases with roentgenograms of normal spines as in the cases with abnormal roentgen changes. It is the author's theory that low back pain with radiation of pain into the leg is a clinical syndrome arising from a primary lesion in the lumbar, lumbosacral or sacro-iliac region, muscular, joint or skeletal in origin, producing a radiation of pain by a referred mechanism which is typically postaxial in its distribution. The lack of evidence of true organic nerve injury in 79 per cent of cases is in favor of referred pain. The predominance of reflex changes and sensory changes in the cases showing narrowing of the lumbosacral disk suggests that in this type of lesion direct irritation of the nerve roots may develop in addition to the referred pain. The area of tenderness may also be the result of referred pain through irritation to the sensory nerves of the ligamentous structures rather than indicative of underlying pathologic changes of the joint.

Cod Liver Oil in Skin Ulcerations—Epstein describes thirty-one cases of ulceration of the skin treated by the local application of cod liver oil and anhydrous wool fat dressings, with discouraging results. Slight ulcerations were treated with anhydrous wool fat alone. There were 22 per cent more varicose ulcers in the control series, and there were 22 per cent fewer ulcers of more than one year's duration. The one ulcer that had persisted for thirty-five years made the average duration greater in the second group. Epithelization proceeded more rapidly with the high vitamin preparation, although healthy granulation tissue was formed equally well with anhydrous wool fat alone. The only complication noted during the use of anhydrous wool fat was the appearance of a new lesion in the area being treated in a patient with a trophic ulcer due to a lesion of the central nervous system. The complications with cod liver oil included an attack of dermatitis venenata that developed after two weeks of treatment and recurred with each subsequent application of the oil. This patient also had associated stasis eczema. An infection with *Bacillus pyocyaneus* occurred in another patient and did not improve with further applications of cod liver oil. An ulcer that recurs after being "healed" with either of these preparations does not respond as well when treated with the same preparation a second time. "Good" results were obtained in only two thirds of the cases. Cod liver oil alone does not constitute sufficient treatment, as it does not offer permanent results in the majority of cases of ulceration of the skin.

Tuberculin Testing with Purified Protein Derivative—Whitney and McCaffrey base their remarks on a total of 85,709 group tuberculin tests with first and second strength tuberculin (purified protein derivative) among 56,688 individ-

uals in thirty states and the District of Columbia. The adjusted percentage of positive reactors among the 56,688 persons was 47. The adjusted rate was 10 per cent higher than the nonadjusted rate because of the small proportion of adults and persons of foreign extraction included in the groups tested. There were fewer positive reactors proportionately among the 6 year old children tested than there were at any other age. Following the sixth year of life, the trend of infection was generally upward at an average rate of more than 1 per cent for every year of life up to the age of 20. Adults, 20 years of age or older, evidenced 34 per cent more tuberculous infection than the total number of boys and girls less than 20 years of age. The percentage of positive reactors found among the 8,276 persons reported to have had contact with tuberculosis was 54.2, whereas only 33.3 per cent of those with no history of contact responded with positive reactions to purified protein derivative. The infection rate indicated for the contacts less than 5 years of age was three times that for noncontacts in the same age group, but the proportion of positive reactors increased with age, generally at a more rapid rate among the noncontacts than among the contacts. The adjusted percentage of positive reactors for males was 48.3 as compared with 45.9 for females. There was a larger proportion of male than female positive reactors to purified protein derivative at almost every age group. The trend of infection among the Negroes increased with age up to the age of 20 at a faster rate than that among the whites included in the reports studied. Of the 31,318 native born Americans of native parentage, 27.6 per cent evidenced tuberculous infection, whereas 38.4 per cent of the 6,674 native born of foreign stock and 61.2 per cent of the 814 foreign-born responded with positive reactions.

Incidence of Tuberculosis in Silicosis—Examination of 961 quarrymen in the same towns in Massachusetts showed that 219, or 22.8 per cent, showed roentgenologic signs of silicosis. With the reasonable assumption that the tuberculosis mortality, unconnected with silicosis, among these stonecutters is essentially the same as that for males of corresponding age in the community, there still is an excess of eight tuberculosis deaths a year in that group, which may fairly be charged to less than a fourth of the 793 cutters, or roughly to 180, equivalent to an annual mortality rate of 4,400 per hundred thousand, approximately forty times the expected tuberculosis mortality. Since the original examination during the summer of 1933 Pope has found it possible to check the roentgenologic diagnosis of silicosis and tuberculosis in a certain number of quarrymen in one city. Five with that classification have developed positive sputum, and three others who have come to necropsy all showed definite macroscopic and microscopic evidence of coexisting silicosis and tuberculosis. The fact that the diagnosis of silicosis or of silicosis with tuberculosis is often made on insufficient evidence or by inexperienced physicians in no way detracts from the importance of silicosis as an industrial disease or from the demonstrated frequency or seriousness of tuberculosis as a complication of silicosis.

Lesions of Fundus in Polycythemia—Cohen finds that examination of the fundus in polycythemia is likely to reveal early characteristic lesions which are of value in diagnosis.

The fundus sometimes appears normal, while at other times lesions exist, which may be mild or severe, depending on the severity of the disease and whether or not the patient has responded to treatment. The existence of a high red cell count of the blood, with a corresponding increase in the hemoglobin content, frequently determines the degree to which the fundus is affected and also the extent of the vascular changes in the conjunctiva and iris. The vascular lesion of the fundus is a part of the general vascular disturbance which is not of an inflammatory nature. The characteristic change in the fundus in polycythemia is marked distention and engorgement of the retinal veins, which appear purplish. This distention is due mainly to an increase in the blood volume and a thinness of the venous wall. The change in color is caused by excessive replacement of oxygen by carbon dioxide. The resultant venous stasis is the basic factor in the causation of the ocular lesion. Seven cases of polycythemia are reported, in two of which there were no fundic complications. In two there were lesions of the fundus, while in three the lesions were solely vascular distention of the retinal veins, which were purplish and moderately tortuous. The fundic complications in the two cases of primary polycythemia were as follows. One case presented venous engorgement in one eye, with edema of the disk and retinal hemorrhages, the other showed bilateral postneuritic atrophy of the optic nerve, with distended veins which were bordered by a distinct broad whitish band along the perivascular space, due to a transudation of plasma. The perivascular space of the retinal arteries was not involved.

Blood Pressure in Pulmonary Tuberculosis—Kennedy studied the blood pressures of eighty-five patients having far advanced tuberculosis for at least three months, and the period of active study varied from three to seven months. A well maintained blood pressure is of favorable prognostic import, whether consistently high or low. The degree of blood pressure response to cold gives a more accurate standard for measuring cardiovascular tone than does the ordinary series of single blood pressure determinations as far as the prognosis in pulmonary tuberculosis is concerned. A response of 8 systolic, 4 diastolic mm of mercury would seem to be the least rise in blood pressure compatible with a healing case. Patients with

pulmonary tuberculosis, minimal to far advanced, who do not heal rapidly, or who tend to show exacerbations, give a poor blood pressure response to cold. In repeated cold tests, when spread of disease in the lung has occurred, the response to cold usually is impaired definitely before there is any drop in basal, or pretest, blood pressure. The cold test should be applied as a routine in all cases of pulmonary tuberculosis in which the highest systolic blood pressure by ordinary morning determinations is not more than from 120 to 126 mm of mercury. Absence of a rise in diastolic pressure in response to cold implies a definitely unfavorable course of tuberculosis, unless the systolic rise is quite marked.

Acetylsalicylic Acid Therapy of Chorea—Pearson employed calcium and acetylsalicylic acid in the treatment of twenty-three cases of Sydenham's chorea with marked clinical improvement and a shortening of the average duration of the chorea. Spinal fluid calcium estimations in the twenty-three cases of chorea showed that there was no minimal figure below which chorea occurred. Variations in the calcium level in the spinal fluid during the attack of chorea were found to range from 26 to 64 mg per hundred cubic centimeters and after the chorea had subsided they ranged from 28 to 66 mg. With calcium and acetylsalicylic acid treatment seventeen cases of chorea showed an increase in the calcium of the spinal fluid, with a disappearance of the chorea, six cases showed a decrease in the spinal fluid calcium, also with a disappearance of the chorea. Many of the cases showing an increase later showed a decrease to the former level or below it with no return of the chorea. Some patients returned to the hospital several months after discharge with a recurrence of chorea, although the level of the spinal fluid calcium remained the same or was higher than on discharge.

Etiology, Symptoms and Treatment of Delirium Tremens—Hilton asserts that countries which rigorously restrict the per capita consumption of alcohol have a low rate of incidence of delirium tremens, the distinctive symptoms of which are delirium, tremor and sometimes peripheral neuritis. Unless interrupted, physical restlessness may lead to collapse and death. Sleep should be induced immediately. The drug of choice is paraldehyde in doses of from 3 to 6 drachms (12 to 24 cc). As soon as the patient is asleep a spinal puncture should be done and from 20 to 50 cc of spinal fluid should be withdrawn in order to relieve the cerebral edema and reduce the spinal fluid pressure to an approximate normal. Following

the administration of the paraldehyde and the spinal puncture the patient sleeps soundly for from four to eight hours and awakens free from the delirium, or at least oriented sufficiently so that he correctly interprets his environment and responds to nursing care. If this or a similar procedure is not carried out the delirium will persist and exhaustion or intercurrent infection may bring about a fatal outcome.

Intestinal Obstruction Due to Gallstones—Cameron emphasizes the frequency of gallstone ileus and the need for its early recognition. He cites the history and operative procedure in two such cases with recovery and subsequent x-ray study of the gallbladder. A third case, seen only at necropsy, is also reported. In one of the cases in which operation was performed a gallstone half an inch in diameter was vomited a few minutes preceding the operation. In sixty-one cases of mechanical ileus, excluding strangulated hernias, in which operation was performed by the author, the obstruction was

caused by gallstones in two instances, a frequency of 33 per cent. Owing mainly to the early recognition of the obstruction, both of these patients recovered. The gallstones gain entrance to the intestinal tract through a fistula from the gallbladder. The shortest diameter of the obstructing calculus is about 1 inch. Apparently larger stones seldom reach the intestine and smaller ones do not cause obstruction. X-ray study of one case seven years after operation showed that the gallbladder filled and emptied normally. A gallstone ileus should be strongly suspected in any patient, especially a woman, in whom an acute obstruction of the small intestine develops suddenly after an exacerbation of chronic gallbladder disease.

The Heart Throughout Various Periods of Life — Willis considers the heart in relation to the ten decades of life and records the incidence of its major diseases and their modifying influence on longevity as derived from a study of 3,418 cases, in 60 per cent of which postmortem examinations were conducted. The eight principal forms of heart disease were represented: coronary disease, hypertensive heart disease, rheumatic heart disease, syphilitic cardiovascular disease, adiposity of the heart, chronic adherent pericarditis, calcareous aortic stenosis and congenital heart disease. The relative incidence of the various forms of cardiopathy were as follows: coronary disease, 33.5 per cent, hypertensive heart disease 26.8 per cent, rheumatic heart disease, 27.2 per cent, syphilitic cardiovascular disease, 6.3 per cent, adiposity of the heart, 2 per cent, chronic adherent pericarditis (nonrheumatic), 1 per cent, calcareous aortic stenosis, 1.1 per cent and congenital heart disease, 2.1 per cent. The greatest incidence of heart disease occurred in the fifth, sixth and seventh decades of life and 67.5 per cent of the patients belonged to these three age periods. The heart, in the journey through life, is at all times subjected to the perils of disease. These perils vary in character and in magnitude, according to the age of the individual. The heart that has escaped the ravages of disease and has withstood the stresses and strains of active life is one fundamentally endowed with superior qualities. Confirmation of this fact is found in the progressively decreasing incidence of heart disease in the closing periods of life and the consequent diminishing death rate from this cause. This tapering incidence is greatly influenced by the already depleted ranks of aged individuals as the result of many other diseases. That the occurrence of heart disease in the last two decades of life is less than that in the first two decades is not without significance.

Myelination in Nervous System of Rat — Buckley attempted to determine the rate of advancement of myelination in rats treated with thymus extract as compared with normal control animals, to study the regional order of myelination in the central nervous system of the developing animal and to study the comparative behavior capability in the two sets of animals. Allowing for difference in rate of growth in individual animals, there appeared a consistent similarity in control animals of similar age. The 6 day thymus treated albino rat of the sixth generation shows myelination in the spinal cord equivalent to that of the normal 13 day or older animal, the 6 day thymus treated rat of the tenth generation shows myelination equivalent to that of the rat 20 or more days old. In tenth generation animals, myelination occurs in all funiculi of the spinal cord in thymus treated albino rats at forty-eight hours and at twenty-four hours after birth, except in the corticospinal (pyramidal) and dorsolateral (Lissauer) tract.

*The Probable Nature of the Infectious Agent of Trachoma L A Julanelle R W Harrison and M C Morris St Louis — p 735

Probable Nature of Infectious Agent of Trachoma — Julanelle and his associates made a concentrated effort to determine whether the incitant of trachoma may be considered a virus. As a result of continuing studies on the infectivity of tissues from patients with trachoma, it has been possible to visualize more concretely the infectious agent of the disease.

Adapting to this problem the technic of testicular passage in rabbits, it was found that trachomatous tissues, from both man and monkey, may be purified of the extraneous bacteria usually present on the conjunctiva. While irregular in its execution, this method permits the infectious agent to retain its infectivity a sufficient number of times to support the conclusion that trachomatous tissues liberated of bacteria may still be specifically infectious for monkeys. The evidence indicates, however, that the infectious agent does not multiply during this passage. Successful filtration, employing Scitz, Kramer, Berkefeld and Elford filters, is accomplished only rarely and with difficulty. It may be that filtration of the infectious agent depends on a certain degree of epithelial cell degeneration for its liberation into the surrounding menstium. Since cellular degeneration is slight, particularly in the uncomplicated stages, it is not unlikely that the unattached infectious agent occurs in quantities insufficient for successful filtration. In the rarer cases of marked cellular degeneration on the other hand, the infectious agent is filtrable thus contributing the few examples reported in the literature. Inability of the infectious agent to multiply in various bacteriologic mediums suggested attempted propagation in tissue cultures. The conclusion is inevitable that the infectious agent of trachoma possesses an exquisite tissue specialization. Unable to infect lower animals at all the modified disease it induces in apes and monkeys is confined to the conjunctiva. On careful reflection, the evidence suggests that the infectious agent of trachoma is a virus, filtrable with difficulty, under conditions not yet understood. Its characteristics of low infectivity, marked tissue specialization, poor immunogenic properties, rare filtrability, weak propagative power and fragility before different agents all classify the virus as an extremely unusual variety. Indeed, even the inclusions accompanying its presence in human tissues differ from the virus inclusions heretofore recognized. If future investigation succeeds in confirming its viral nature, it will have to be regarded as possessing properties differing considerably from those of viruses now generally known.

Hemolytic Streptococcus Toxins and Antitoxins.—Rane and Wyman developed a flocculative test for the titration of hemolytic streptococcus toxins and antitoxins which is comparable to the Ramon method for titrating diphtherial toxins and antitoxins. The technic employed in flocculation is essentially that of the Ramon test. Concentrated toxins are preferred to crude toxins because they flocculate with greater rapidity. One unit of antitoxin will combine in the flocculative reaction with 60,000 skin-test doses of toxin instead of with the 50 skin-test doses to be expected on the basis of the definition of an *in vivo* unit of antitoxin. This relationship has been true of all toxins tested except those modified by formaldehyde. Streptococcus toxins and antitoxins display individual variations in their flocculating time and are influenced by the same factors as diphtherial toxins and antitoxins. The flocculating antibody is produced in horses in amounts which parallel the antibody produced against the erythrogenic toxin. It is possible that the two antibodies are identical. The average of the *in vivo*/*in vitro* ratios was found to be 0.963. The correlation-coefficient of the values obtained by the flocculative test and by the intracutaneous test in rabbits was 0.947 ± 0.023 . The Dochez NY 5 strain of hemolytic streptococcus was used as the basis for this study, although flocculation was produced with other strains of hemolytic streptococci and their homologous antitoxins.

"Toxic" Postpartal Heart Disease.—Hull and Hafkesbring point out that congestive heart failure not due to any of the usual types of heart disease sometimes occurs in women shortly after the termination of a pregnancy. The causes of the failure are believed to be factors that operate during pregnancy or the puerperium or both. This type of heart disease has tentatively been termed 'toxic' postpartal heart disease. It closely resembles the cardiac form of beriberi in symptoms and signs, and it is believed that relative food deficiencies probably are concerned in its pathogenesis. Other possible etiologic factors are the hypertension, hypoproteinemia and water retention of the toxemia of pregnancy, the tendency to edema present in normal pregnancy and puerperal infection. This condition offers a better prognosis than heart failure of similar severity due to the usual causes, and complete restoration of the heart to normal is apparently possible. Symptoms appear at a variable time after parturition, most frequently within a month. The onset is usually gradual, early symptoms being swelling of the feet and ankles, slight dyspnea and cough. Edema gradually increases, so that after a few weeks it is extreme, involving the face and arms as well as the legs, large effusions are present in the pleural and the peritoneal and sometimes in the pericardial cavities. The triad of anasarca, gallop rhythm and small volume pulse is characteristic. Laboratory data are inconclusive. The incidence of postpartal heart failure might be reduced by the prescription of diets for pregnant women which are adequate in protein, iron and vitamins. The slightest symptoms of cardiac embarrassment during the later months of pregnancy or after the puerperium should call for rest in bed, restriction of the intake of fluid and salt and a high protein and high vitamin diet. Although the response to the usual measures used in the treatment of heart failure is not striking, it is hardly justifiable to omit these measures. The patient should be digitalized, his intake of fluid and salt should be restricted, and diuretics should be employed. Venesection is of benefit when dyspnea is extreme. Measures directed toward correcting possible pathogenic factors are also indicated.

Report of the Pasteur Institute of the Charity Hospital of Louisiana at New Orleans for the Year 1936 R D Aunoy and J H Connell New Orleans—p 643

Pyogenic Osteomyelitis of the Spine—Mayoral reports a case of pyogenic osteomyelitis of the spine in which, although osteomyelitis was suspected and the patient was repeatedly roentgenographed, the lesion was not found until he had practically recovered. In the spine, as in any other bone, roentgen diagnosis of osteomyelitis cannot be made before there is bone destruction, and it is at best a late diagnosis. The time at which bone destruction becomes visible in a roentgenogram depends on the "balance of power" between the aggressiveness of the infectious organism and the body resistance, and, to a certain extent, on the site of the infection. Therefore roentgenograms cannot be of aid in making an early diagnosis, but, like postmortems and biopsies, they can be confirmatory. The clinician should be familiar with the limitations of the roentgenogram so as not to place too much emphasis on negative observations. The burden of proof in early diagnosis rests on the clinical signs and symptoms. When metastases lodge in the vertebrae, two types of symptoms develop: septic, accompanied by a high leukocyte count, polymorphonuclears predominating, fever, malaise, muscular pain, headache and vomiting, and the localized symptoms of infection within the bone which cause pain and early disability of the section of the spine involved. Later symptoms depend on the behavior of the local infection. Osteomyelitis is generally a metastatic lesion. If the original focus is found, the relationship between the primary and secondary foci can be established. The etiology can then be reasonably suspected and proved by biopsy, culture or animal inoculation. When these classic methods cannot be applied and when the spinal lesion develops from a hidden, inactive focus, the problem is entirely a clinical one. A rapidly disabling and painful, localized lesion showing marked signs of inflammation accompanied by leukocytosis and rapid bone destruction is a factor pointing to pyogenic infection, in contradistinction to tuberculosis, which is a chronic disease destroying bone slowly.

Jaundice—Heyd states that jaundice with pain and bile in the stool or duodenal drainage denotes calculous or infectious obstruction of the external biliary system. Jaundice without pain and without bile in the stools or duodenal contents indicates carcinoma of the external biliary system. Jaundice without pain, but with bile in the stool or duodenal drainage, suggests intrinsic pathologic changes of the liver. Hemolytic jaundice, familial jaundice and the jaundice of the anemias are termed "dissociated jaundice" in that there is an excess of bilirubin in the blood, but no retention of bile salts or bile acids, and the excretory function of the liver for the delivery of bile into the intestinal tract is normal. Gallstones, however, may be found at laparotomy in patients with hemolytic jaundice because there is "bile retention" in the intrahepatic bile ducts due to the excess

of bile pigments, with an inability of the liver to excrete this excess. Bile thrombi occur in the intrahepatic bile canaliculi and there is a deposition of bile pigments in the gallbladder with the production of pleochromic calculi.

Attacks of Acetonemic Vomiting from Ketogenic Diet—Heymann emphasizes that loss in weight and early and severe ketosis, together with the precipitation of uncontrollable vomiting, are specific, that is, they are found only in true acetonemic vomiting. It has been claimed that hypoglycemia is an essential element in cyclic vomiting. However, he found that normal, healthy children, from 3 to 10 years of age, who were placed on a practically carbohydrate free diet, developed the same degree of hypoglycemia that is developed by children during an attack of cyclic vomiting. Therefore the low blood sugar values occasionally found in cases of cyclic vomiting must be due to the carbohydrate starvation obviously present in children who are vomiting and starving. Furthermore, this hypoglycemia may be compensated, depending on the degree of dehydration that often accompanies an attack of cyclic vomiting. Because of the sudden development of hypoglycemia and acetonuria in children suffering from recurrent acetonemic vomiting, it has been thought that the inability of the liver to hydrolyze glycogen might be the cause of the attack. However, the intramuscular injection of 0.5 cc of epinephrine caused a normal rise in the blood sugar value in such a child on a day when the child was healthy as well as on another day just one hour before an attack of cyclic vomiting started. That the once increased blood sugar does not return to normal values in the proper time is most probably a consequence of dehydration. On the basis of observations that children suffering from recurrent acetonemic vomiting develop ketosis and severe dehydration easily under the influence of a ketogenic diet, the author thinks that he is justified in assuming some abnormal regulation and extreme lability of the intermediary carbohydrate metabolism, and perhaps also of the fat metabolism, of the liver. That the accumulation of ketone bodies does not represent the substance responsible for the development of uncontrollable vomiting is rather certain. A decreased glycogen storage in the liver involves a faulty utilization not only of fat but also of protein.

Prognosis in Coronary Heart Disease—King saw 112 patients with coronary heart disease and coronary occlusion. Sixty-two were seen at the time of the acute occlusion and fifty were seen later. The occurrence of an initial shock, auricular fibrillation, persistent high fever and marked leukocytosis at the time of the occlusion influences the prognosis unfavorably. In cases observed some time after recovery from the acute occlusion the appearance of paroxysmal nocturnal dyspnea, acute pulmonary edema and congestive failure, especially with a slow heart rate and normal rhythm, and the presence of considerable cardiac enlargement or anginal attacks on slight exertion indicate impending complete failure. Auricular fibrillation appearing late in the course of coronary heart disease does not materially alter the outlook for the length of life.

*Dibenzanthracene Tumors in Mice Production of Subcutaneous Pulmonary and Liver Tumors by Serum Dispersions and Lard Solutions H B Andervont and E Lorenz —p 637

Dibenzanthracene Tumors in Mice—Andervont and Lorenz injected dog serum and horse serum dispersions of 1,2,5,6-dibenzanthracene intravenously or subcutaneously and lard solutions of the same compound were injected subcutaneously into pure strain mice. The serum dispersions, when injected intravenously, induced lung and liver tumors, and, when injected subcutaneously, produced local tumors at the site of injection as well as lung and liver tumors. Lard dispersion, when injected subcutaneously, evoked local tumors at the injection site and also produced lung and liver tumors. The appearance of lung and liver tumors in mice injected subcutaneously is evidence that 1,2,5,6-dibenzanthracene is capable of producing tumors in tissues which are distant from the site of injection.

Protamine Insulin—Smith and McKeown treated fifteen ambulatory patients having uncomplicated diabetes mellitus with protamine zinc insulin. These patients were divided into three groups according to the time of day protamine was used. All were taught to keep an accurate check on the sugar content of their urine, testing four or five specimens daily. Diets were adjusted to the individual patient. The administration of protamine insulin was started by a gradual substitution of approximately 70 to 80 per cent of the required dose of the old insulin and gradual alteration of the dose of old insulin, as indicated by the sugar content of the blood or urine. The greatest reduction in the number of units of insulin required was in the group receiving protamine zinc insulin twice daily. The greatest reduction in the number of daily doses required was in the group receiving protamine in the morning. In the group receiving protamine morning and evening only, 33 per cent of the patients dropped one dose a day, with an average reduction of 12.5 per cent in the total number of daily doses required. In some cases control with protamine was accomplished within a few days, but on an average it required from four to six days for the full effects of a given daily dose of protamine to show its maximal effect. Only a few minor hypoglycemic reactions were encountered. All the patients reported from slight to marked improvement in subjective symptoms. If hypoglycemia occurs, it is usually mild but much more prolonged.

Colectomy or Colonic Exclusion with Ileostomy—Whittaker and Borgen studied both the immediate and the late effects of total colectomy or colonic exclusion on forty five patients. Colectomy or colonic exclusion by ileostomy was done only after conservative treatment had failed. The three most frequent indications were refractory chronic ulcerative colitis, chronic ulcerative colitis with polyposis, stricture or perirectal abscess and hereditary polyposis. The values for the serum calcium were slightly reduced following colectomy or ileostomy but returned to normal within a month. Colectomy or ileostomy does not otherwise disturb the physiologic equilibrium of the chemical constituents of the blood. Roentgenologic visualization or the appearance of the terminal portion of the ileum at operation or necropsy revealed a definite dilatation. There was no evidence that the dilatation was sufficient to compensate volumetrically for the excluded colonic reservoir. Stools from the ileac stomas were alkaline. The average weight of the stools while the patients were on a general diet was 433 Gm and the water content was 91.2 per cent. The watery discharge gradually thickened during the first three months. This thickening of the stool is unrelated to the time necessary for the ingested material to be expelled from the ileac stoma. There was no fundamental change in motor activity or in the intestinal response to the ingested food throughout the prolonged period following operation. A period of three months is necessary for the patients to regain their average weight and strength. No permanent deficiencies in metabolism follow ileostomy.

Pitressin in Laparotomies—Seed and his collaborators state that the three most important effects of pitressin in man are the stimulation of intestinal peristalsis, the reduction of kidney excretion and the pressor influence on the cardiovascular system. Pitressin in 20 unit doses produces powerful contractions of the distended colon with expulsion of its contents. Doses of 10 units are preferable in normal individuals, because they are only a little less effective and cause much less distress. The blood pressure generally rises after an injection of pitressin, but the rise is not large or long sustained, the deleterious effects of pitressin on the heart or blood pressure do not occur with ordinary therapeutic doses. The intravenous route of administration is not advisable. The tendency to a decreased urinary output is not sufficient to be of clinical importance, except possibly in patients with an already damaged urinary system. Pitressin given in 10 or 20 units, combined with a rectal tube is effective in postoperative atony. Pitressin given preoperatively has a tendency to contract the intestine. Its routine use after operation tends to reduce somewhat the amount of dis

tention and discomfort following operation. Neither effect is sufficiently important to make its use in this manner mandatory. The postoperative treatment of peritonitis consists largely of the use of parenterally administered fluids, constant gastric siphonage and morphine. A patient with peritonitis will recover or die, regardless of whether he does or does not receive pitressin.

Arsenoxide in Treatment of Early Syphilis—Parsons treated twenty-five cases of early syphilis with alternate courses of arsenoxide and bismuth compounds. They have been under observation and treatment from ten to twenty-three months, the average being sixteen months. None had received prior antisyphilitic treatment. The age of the infections (appearance of primary lesion to beginning of treatment) ranged from one to seventy-eight days, the average being seventeen days. Twenty had positive darkfields, and of these, fifteen had positive Kahn tests before treatment was started. The darkfields became negative in from one to five days after the first injection, the average being 1.5 days. Three with primary lesions had negative darkfields but were diagnosed by other means. Three had healed chancre on admission and were diagnosed by other means. Among the twenty-one positive Kahn cases, twenty became negative after from four to twenty injections, the average being 8.9 injections. The other case remained 4 plus until twenty injections each of mapharsen and a bismuth compound had been given and then remained 2 plus until thirty injections of mapharsen had been given. It has since remained negative. No instance of clinical and only one of serologic relapse has been observed. Twenty-two patients have completed one year's treatment, including thirty injections each of arsenoxide and bismuth salicylate. Spinal fluid examination (after a year's treatment) has been accomplished in nineteen of the twenty-two cases in which the spinal fluid was negative in all phases. Nothing but the most negligible types of reaction were seen. Mild Herxheimer reactions were observed following the initial dose in two secondary cases and one late primary case. Subsequent injections produced no further reactions in any of these three cases.

*Milk's Warts Infection from 'False Cowpox' with Paravaccinal Virus P Bonnevie—p 164

"Milk's Warts"—Bonnevie presents four cases and gives a description of the clinical and pathologic features of milk's warts—presumably a disease entity. Among the eruptions on the teats of the cow there is a bullous-verrucous condition which is generally called pox. It may give rise to epizootics, especially in the summer. It may be transmitted to man and thus cause small epidemics. The infection produces characteristic granulomatous efflorescences at the sites of inoculation on the hands, so-called milk's warts, in some cases complicated with secondary, more or less extensive exanthems, the elements of which correspond to abortive milk's warts of more vacuiform appearance. The lesion disappears without treatment within a few weeks and without leaving any trace. Probably the infecting agent is a filter-passing virus closely related to variola-vaccinia, Strongyloplasma paravaccinia (Lipschütz), which is known as the producer of 'vaccine rouge,' paravaccinia (Pirquet). The disease may be seen also in slaughter-house workers, and it occurs in other animals besides the cow, e.g., sheep.

Type of Clostridium Welchii in Human Feces—Borthwick and Gray state that all the five strains of Clostridium welchii isolated from the feces of patients suffering from pernicious anemia produced toxins of the A type, as shown by the short period of incubation required to produce the optimal concentration of toxin and the neutralization of the toxins by any of the four standard type antitoxins. Of five strains from the feces of healthy persons, two were either completely or practically nontoxic and the other three produced toxins of the A type. Differences between the toxins of the strains from the two sources could therefore not be elicited other than in the degree of toxicity. Toxin when produced in amounts suitable for testing, was consistently of type A. Evidence therefore is still lacking that man harbors Clostridium welchii of types other than type A.

Insulin Shock Treatment of Schizophrenia—All the cases of schizophrenia treated by Larkin with the daily insulin shock method have been advanced cases with marked symptoms.

of dementia praecox. Five patients have completed treatment. Three have apparently recovered. The other two are still being watched, their insight being developed by daily talks with a view to their adapting themselves well to life when they shall have returned to the outside world. Of the two who have not recovered, one is greatly improved and the other is unchanged. All except the one patient in whom the treatment was not beneficial have put on weight while actually under treatment. A sixth has already lost his delusions and hallucinations, after an unremitting attack lasting eighteen months. The starting dose of insulin is 20 units intramuscularly, the patient fasting. This is increased daily by 5 or 10 units according to progress. A shock dose is usually 130 units. Subsequent shocks are easier to induce than the first, and after a few days it may be possible to reduce the dose considerably.

Hypertension Associated with Experimental Serum Nephritis—Arnott and his colleagues made a study of the hypertension that accompanies serum nephritis, the effect of previous renal denervation on the intensity of the renal lesion, on the hypertension and on an established hypertension. The results confirm those obtained with oxalate nephritis (Arnott and Kellar, 1936) and strengthen the contention that the hypertension of acute diffuse renal disease depends for its occurrence on the integrity of the renal nerve supply. This points to two possibilities (1) that the hypertension is produced by an autonomic vasoconstrictor reflex originating in the damaged kidneys or (2) by some chemical mechanism which depends for its operation on the integrity of the renal nerve supply. There is at present no collateral evidence in support of the second hypothesis, whereas the first hypothesis receives confirmation from work by Pickering (1936) on the nature of the arteriolar hypertonicity in human cases of acute glomerulonephritis. He used the same methods which had already led him to the conclusion that the chronic hypertension of advanced nephritis and essential hypertension was not due to excessive nervous vasoconstrictor tonus. These methods applied to a series of cases of acute glomerulonephritis led to the opposite conclusion—that the hypertension was due to an abnormal degree of such tonus. The authors believe that these results of Pickering may also throw light on the discrepancy between their results and those of Page (1935) and Collins (1936), who found that the hypertension produced by constriction of the renal artery could not be prevented by previous renal denervation. This hypertension was probably of the chronic type and is more comparable with the chronic hypertensive states of advanced renal damage than with the hypertension of acute renal disease. It may well be that integrity of the renal nerves is necessary for the production of acute renal hypertension only.

Treatment of Tuberculosis of Kidney—Jacobs considers any patient with pyuria and a tubercle-positive urine in the absence of a genital lesion to be suffering from a renal tuberculosis. If a genital lesion is present, this should never be accepted as the source of the urinary infection for an investiga-

tion of the upper part of the urinary tract will show that the greater number of these patients have a coincident renal lesion. When the diagnosis of urinary tuberculosis has been established it is essential to ascertain whether the disease is unilateral or bilateral. If it is unilateral, a nephrectomy must be carried out as natural healing of the lesion cannot occur. The presence of tubercle bacilli, without pus in the urine, from a kidney which has a normal pyelographic outline should not contraindicate the removal of the other kidney if it is the seat of an established destructive lesion. The presence of other tuberculous lesions should not be a deterrent to nephrectomy except when they render the patient too ill to stand the operation. Removal of the kidney should be regarded as only an incident in the course of the treatment. After operation, all patients should undergo a prolonged sanatorium regimen. Inoperable bilateral cases should have sanatorium treatment. Although a cure cannot be expected, the defense mechanism of the body may be built up to such a degree that some control of the lesions may result. If this is successful, bilateral disease may be compatible with life for a number of years.

Weight Changes During and After Pregnancy—McIlroy and Rodway had under constant observation 704 primigravidae and 296 multiparas from the twenty-fourth week of pregnancy to term. The average periodic gain in weight was 11 pounds 2 ounces (5,046 Gm) for the primigravidae and

11 pounds 7 ounces (5,188 Gm) for the multiparas. The maximal increase occurred from the twenty-fourth to the twenty-eighth week, 3 pounds 5½ ounces (1,517 Gm), and the minimal increase from the thirty-eighth to the fortieth week, 2 pounds 4 ounces (1,020 Gm). The age of the patient has an influence on the gain in weight in pregnancy. The older the patient, the less increase there is in weight. Parity has little or no influence. Heavy patients showed less gain in weight than those of lighter build. The weight of the infant seems to have little influence on the changes in the maternal weight. The infants of primigravidas were rather heavier if the maternal weight showed much increase. Decrease in weight occurs during the last two weeks before delivery in a number of cases, 22.5 per cent in primigravidas and 22.15 per cent in multiparas. A few patients showed a periodic loss of weight throughout pregnancy. This may be due to tissue loss owing to excessive fetal demands, although these patients did not show any marked evidence of malnutrition. In the seventy-five cases of toxemia in the 1,000 cases the average age was 33 years. Albuminuria, a systolic blood pressure of 140 mm of mercury and edema of varying degrees were present in all. The average periodic gain and the total increase of weight were greater in this group of cases. From the twenty-fourth to the thirty-eighth week the gain in weight was 50 per cent greater than in the normal cases. During the last two weeks of pregnancy it was almost three times as much as in the series of normal cases. The total gain was one and a half times that of the nontoxic cases. Excessive gain in weight may also be due to edema of the tissues, although not evident on clinical examination until later. Some toxic patients, however, had marked edema without excessive gain in weight. The prevention of toxemia and the early recognition of signs of its onset are to be obtained by careful attention directed to the routine weighing of antepartum patients. Of 710 patients weighed approximately six weeks after delivery the primigravidas showed an average loss in weight of 21 pounds 5 ounces (9,667 Gm) and the multiparas 18 pounds 14 ounces (8,562 Gm). The birth weight of the infant accounted for one third of the decrease in primigravidas and two fifths in multiparas.

Intrapartum Infection—Anderson states that in a series of 11,075 deliveries at the Johns Hopkins Hospital 207 instances of intrapartum infection occurred, an incidence of 1.9 per cent. Of the 207 cases 33½ per cent occurred among white patients. Whereas in the clinic 34 per cent of the normal patients had vaginal examinations, 56 per cent of the patients having intrapartum infection were thus examined. 56.3 per cent of the maternal deaths in the series were in patients who had been examined vaginally prior to admission to the hospital by their own medical attendants. The character of the labor pains was judged to be satisfactory in 50.2 per cent of the cases. The onset of labor was spontaneous in 77.8 per cent, while induction other than by drugs was performed in 22.2 per cent. The operative incidence for the hospital population (obstetric department) was 22.9 per cent, while in these cases of intrapartum infection it was 48.8 per cent. Both the maternal mortality and the fetal mortality were more than twice as great in the patients subjected to operative procedures. In the cases of intrapartum infection the incidence of manual removal of the placenta was 4.3 per cent as compared with 0.8 per cent in the service as a whole. The mean loss of blood was greater and the incidence of postpartum hemorrhage more than double that noted in normal patients. Whereas 17.5 per cent of the total number of patients in the service developed puerperal infection, this complication occurred in 57 per cent of the cases of intrapartum infection. With an intrapartum elevation of the temperature to 100.8 F or less there was no maternal death, nor was there a fatal result in cases in which the pulse rate did not exceed 100 per minute during labor. The average duration of labor was considerably greater in cases of intrapartum infection than in the service generally. Only one maternal death (6.3 per cent) occurred when the membranes had been ruptured for less than twelve hours prior to delivery. The maternal deaths in the series numbered sixteen (77 per cent). Seven (43.8 per cent) of these occurred within twenty-four hours after delivery and ten (62.7 per cent) within ninety-six hours. Conservatism is advocated in dealing with cases of intrapartum infection.

Pathology of Adrenal in Relation to Sudden Death—

In discussing the effects of disease of the adrenals, Simpson summarizes certain of the facts known about their developmental anatomy and physiology. Pathologic changes in the body after death from acute insufficiency of the cortex are, for practical purposes, limited to those by which the gland itself is destroyed. Dilatation of the heart, congestion of the lungs or pancreas or other organs, and the presence of bile in the gastric contents have been noted in addition and even credited with some significance in relation to sudden deaths, but these are general changes. The systemic reflections of cortical insufficiency are almost entirely biochemical and attended by functional disorder rather than by any structural change visible to the eye. Even in the gland itself there are but few morbid processes to be found with any frequency under these conditions, three are commonly seen, others rarely. The three common changes are hemorrhagic necrosis or hemorrhagic infarction, acute caseative tuberculosis and rapid metastatic growth invasion of the gland. It is in the examination of changes in the chemistry of the blood that the causes of death become apparent. They are related principally to alterations in hepatic and renal function consequent on deprivation of the essential cortical hormone. Those changes consequent on diminution of hepatic function are reflected in a rise in the cholesterol and a fall in blood sugar. Diminution of kidney function, related clearly to dysfunction of both glomerular and tubular elements, is reflected in a sharp rise in blood urea and other nonprotein nitrogen constituents of the blood the urinary output being decreased. The blood volume is reduced, together with the levels of both sodium and chloride, the urinary output of these substances vastly exceeding the intake over any period after the second day. There is no deviation of fluid into the tissues, which become dehydrated, and no passage of fluid into the red corpuscles these becoming increased in number as the blood concentrates. Sodium diminishes by as much as 15 per cent, potassium values increase by as much as 42 per cent and magnesium by as much as 23 per cent, effectively maintaining the falling osmotic pressure. The chloride loss is relatively less than that of sodium. This results in a decrease in bicarbonate and a disturbance in the acid-base equilibrium the pH falling. In some respects the conditions are analogous to those of hypocalcemia after deprivation of parathyroid, and in this respect it would not be unreasonable to attribute to the adrenal cortex the control of sodium.

Diphtheritic Myocarditis—Begg investigated 100 cases of severe faucial diphtheria electrocardiographically. The average day of death in this series from circulatory failure early or late was the tenth day of disease, and the latest day recorded was the nineteenth. In only three cases could the associated circulatory failure be described as the early type and two of these showed some electrocardiographic evidence of myocarditis. In contrast deaths typical of late circulatory failure numbered twenty-three and in each case there was electrocardiographic evidence of myocardial involvement with or without the addition of a frank conductive lesion. In 84 per cent of the cases some electrocardiographic abnormality developed as a result of diphtheria, and in no less than 27 per cent this abnormality took the form of a conductive lesion, the mortality in the latter group being more than twice that of the group showing no predilection for the conducting system. In many cases the exact nature of

the abnormality cannot be recognized except by the auxiliary evidence of an electrocardiogram. If complete heart block, bundle branch block or paroxysmal tachycardia appear in electrocardiograms during the course of diphtheria, the outlook as regards recovery is relatively bad. In the presence of other evidence of myocardial involvement, including intraventricular block, the prognosis is reasonably favorable. A normal electrocardiogram, particularly within the first few days of the disease, does not preclude the possibility of a sudden circulatory collapse and, in this respect, clinical examination may be equally misleading. Probably at this stage of the disease an intravenous sugar tolerance curve remains the most sensitive guide to prognosis. Except in a small proportion of conductive lesions, recovery after diphtheritic myocarditis appears to be complete as judged by electrocardiograms taken in convalescence.

Regional Ileitis Crohn's Disease—Seven years ago Hodgson treated a man, aged 51, who came under his care suffering from intestinal obstruction, and at operation the provisional diagnosis of inoperable carcinoma invading the ileum and proximal cecum was made. A lateral anastomosis was performed "to tide the patient over." He rapidly improved, put on 28 pounds (13 Kg), resumed his work—that of a laborer—and was lost sight of. Recently he came under his care again, suffering from a perforated duodenal ulcer, from which he is now recovering. At the recent operation the cecal area could not be palpated for adhesions, and his general condition made speed imperative. Further roentgenography shows "some remaining dilatation of the small intestine, satisfactory anastomosis and filling defects in the terminal ileum and proximal cecum amounting to the 'string sign'—a thin irregular linear shadow running through the filling defect." This string sign is described as characteristic of Crohn's disease. The case suggests that simple short-circuiting is sufficient in certain cases and should be considered when the infiltration of the mesentery renders total excision dangerous.

Sporadic Case of Bacillus Enteritidis Septicemia—Frank states that sporadic cases of Salmonella infections may not be correctly diagnosed unless agglutination tests are done. Occasionally these infections develop without producing any disturbance of intestinal function. This has happened in infants and young children in whom the meninges have been affected. A case of Salmonella infection due to Bacillus enteritidis of Gartner is reported. The typical onset with symptoms of acute gastro-enteritis was soon followed by septicemia, and on the eighteenth day of the illness a right basal pneumonia developed. The severity of the illness and the amount of offensive sputum suggested the diagnosis of suppuration of the lung. On two occasions thick pus was aspirated from the lower lobe of the right lung by paracentesis of the thorax. The diagnosis was made by the recovery of Bacillus enteritidis from the blood stream and feces, and later from the sputum and the pus aspirated from the right lung. In addition there was a positive agglutination response of this organism, isolated from both feces and blood stream, to the patient's own serum in the high titer of 1:1,280. In obscure febrile illnesses it therefore appears essential to do the agglutination reaction against the Salmonella group if the common tests against the typhocolon and the Brucella group should fail to yield a reaction. Although no definite proof of the source of infection in this patient was dis-

covered, it appeared most likely to have been due to eating two lightly fried duck eggs two hours before the sudden onset of the illness. Early treatment is mainly eliminative, once dehydration sets in, adequate administration of fluids is indicated. In the case recorded, fluid given intravenously by the continuous drip method for eight days undoubtedly saved the patient's life. The patient recovered completely.

Specific Antivenene in Treatment of "Knoppie-Spider" Bite—Finlayson summarizes the results of eighteen cases of spider bite treated with serum. When serum was issued to physicians, in view of the experimental nature of the treatment they were advised to administer the antivenene by subcutaneous injection. In two cases however, a physician injected serum intravenously with no ill effects and it would appear that this route is to be preferred in serious cases. All the eighteen patients treated recovered, and although in some patients morphine and atropine were injected in addition to the serum, records of eleven patients treated with serum alone are available. Several patients were in a state of collapse when the serum was administered but recovered within twenty-four hours after serum administration. Since October three fatal cases due to spider bite have been reported in the Cape Province. None of these cases were treated with serum. On the other hand patients treated without serum have recovered. Several of the physicians who used serum were of the opinion that it exercised a beneficial effect on the course of the illness. In one case the patient appeared to suffer from serum shock but recovered without further treatment. Latrodectus indistinctus antiserum neutralizes not only the homologous venom but also that of Latrodectus concinnus.

Diagnosis of Pulmonary Air Cysts—Huber and his asso-
ciates describe a case of pulmonary air cysts in a boy, aged 10
years, whose weight was less than 52 pounds (23.6 Kg).
Purulent pleurisy developed and was drained. The thorax
was underdeveloped and the right side showed a smaller ampli-
tude than the left. The roentgenologic examination revealed
diffuse hypertransparency of the right lung, the right side of
the diaphragm was deformed and its motility weakened. The
heart was displaced toward the right. The pulmonary paren-
chyma could not be detected, and in the lateral and the oblique
views the lung appeared to be irregularly segmented. This
type of cyst easily becomes infected and leads to purulent
pleurisy, which in turn brings about total pneumothorax with
basal adhesions. But what distinguishes such cysts from ordi-
nary pleurisy and suppurated pneumothorax is the absence of
fistulization and of pleural opacities. The differentiation should
be made from bronchial dilatation, purulent pleurisy with sec-
ondary pneumothorax, pneumothorax with secondary infection
and parenchymatous cavity. Their development is usually
benign rarely making surgical intervention necessary.

Unusual Symptomatology in Acute Encephalitis—
Loeper and his associates present the case of a young person
with hemiplegia of the left side with crural predominance,
the condition was slowly progressive and suggested a cortical
lesion due to syphilitic arteritis. It began with lessening of
the muscular force of the lower left extremity, predominating
in the contractor muscles and distal parts. Gradually the upper
left extremity and the facial nerve were affected. Lumbar
puncture and a Wassermann test of the blood gave negative
results. There was some central scotoma. About ten days
later the symptoms became more aggravated, the patient
showed signs of meningitis and had a high leukocyte count
(from 300 to 400 per cubic millimeter, albumin content (0.85
per liter) and sugar content (0.55 per liter) of the spinal fluid.
After a few days the meningeal symptoms disappeared, but the
hemiplegia became spastic. The face was shiny, cold and
expressionless, the patient remained without motion but was
not lethargic. This was mainly a functional paralysis, not
unlike Parkinson's disease, in which the automatic reflexes were
intact. The patient died with signs of bulbar paralysis. In-
cup, respiratory asynchronism in the two halves of the thorax,
frequent vomiting, rapid pulse and, finally, syncope. The
authors state that this was encephalitis based on a syphilitic
disorder, although no syphilitic symptoms were discernible.

Angina Pectoris and Myxedema—Froment and Jeune
maintain that treatment with thyroid extract almost always
aggravates the spasm of the systemic arteries in atheromatous
inflammation of the coronary arteries. As this treatment can-
not influence the cause of the arterial lesions, it only increases
the cardiac output together with the general metabolism. This
treatment is fatal in one third of all cases. The authors begin
with the citation of two cases of myxedema with angina pec-
toris treated with 0.1 Gm of thyroid extract. The dose was

raised to 0.5 Gm and then stabilized at 0.2 Gm. The spastic
crises gradually disappeared completely and the size of the
heart became normal. The two cases have been under obser-
vation for ten years and the spasms always returned as soon
as the treatment was interrupted. These isolated instances are
then confronted with thirteen cases in which even the smallest
daily doses (from 0.03 to 0.13 Gm) elicited violent attacks of
angina pectoris. Only with minimal doses of thyroid extract
(from 0.01 to 0.05 Gm) was it possible to improve the myx-
edema and to space out the coronary spasms. But the arterial
tension was increased in most cases. The contraindications
were the same in women (six) as in men (seven) and it
appears from previous experiments dating back to 1894 that
thyroid insufficiency through the increase of blood cholesterol
favors the development of atheromatous lesions in the arteries
and that degenerative changes due to myxedema may produce
similar lesions. Some authors emphasize the danger of thyroid
treatment because of hyperexcitability of the vegetative system,
while others point out the increased sensitivity to epinephrine
or the increase in cardiac work. Particularly the latter phase,
which causes vasodilatation and thus favors the myxedema, is
dangerous to the damaged coronary arteries. On the other
hand, total thyroidectomy, by lowering the metabolism, by
diminishing organic needs and the cardiac output, may improve
the painful crises, but by increased cholesterolemia favors the
progress of coronary disintegration.

Senility—Assuming that old age is due to progressive
changes in the humoral equilibrium, Brodin and his associates
have examined the urea, cholesterol, uric acid, bile pigments,
arterial tension and blood corpuscles of sixty-one persons rang-
ing in age from 80 to 93 years. They found that urea and uric
acid are not increased. It remains normal after the age of 80,
especially in women. As old age advances, the blood cholesterol
diminishes in most cases. Most authors assert that there is
no relation between the ratio of blood urea and arterial hyper-
tension. The same holds true of blood cholesterol. The authors
found that persons older than 80 years whose arterial tension
was scarcely above normal have a blood cholesterol above
2 Gm, which is the same as in persons whose pressure is dis-
tinctly elevated. The ratio of bile pigments is much increased,
while the number of leukocytes is only slightly changed.
Erythrocytes are decreased in number and have come down
to less than 3,000,000 in some subjects. The authors speak of
senile anemia, which is always the result of some disturbance,
the origin of which is as yet unknown. This anemia runs
parallel with the increased sedimentation speed, which becomes
more pronounced as age progresses.

*Research on Icterus Following Arsenic Treatment M Graffar—p 661
Acute Abdominal Syndrome with Mesocolonic Especially Mesenteric
Adenopathy P de La Marniere—p 664

The Bromine in Gastric Juice—Chatagnon finds that
bromine is a normal and constant product of gastric secretion.
Compared with chlorine it has a small but not negligible part
in the physiologic acidity of the stomach, in the form of hydro-
bromic acid, which at times may become considerable, espe-
cially after the administration of bromine compounds. The
author gathered his experience mainly on subjects deprived of
bromine for many months and subsisting on an ovo-lacto-vege-
tarian diet or on a normal chlorine diet. From these subjects
he collected from 0.087 to 2.57 mg of bromine ions per thou-
sand cubic centimeters. The relation of these ions to the quan-
tity of blood was from 1.5 to 2.2 mg per thousand cubic
centimeters. By administering larger doses of bromine he
found that the bromine secretions of the stomach increased
effecting a partial substitution for chlorine. In all these cases

he noticed that bromine was retained long after the medication ceased and was then slowly eliminated. Parallel with the increase in bromine secretion in the stomach goes increased bromemia. When one is treating gastric ulcers or dyspepsia, one should know that any addition of bromine increases the acidity of the stomach and may bring about phenomena of intolerance.

Research on Icterus—Graffar noticed that pathogenic icterus resulting from the administration of arsenic to syphilitic patients constitutes a controversial subject. In some patients the icterus is toxic and in others a single hepatic relapse or even a simple infection of the liver, which has been weakened by the specific virus and the arsenic. The toxic theory is the least plausible, since most patients can well tolerate new arsenical administrations during jaundice and be cured and after cessation of the icterus continued nearsphenamine treatments will not cause the icterus to recur. But, concerning the hepatic symptoms, it is possible that injections of arsphenamine for syphilis make the liver prone to simple infections which differ little from common catarrhal jaundice. The author mentions seven cases of icterus following treatment by bismuth alone. A differential diagnosis will have to be made from gastro-intestinal disturbances and exantheams which readily disappear with antisyphilitic treatment. Some authors see in this type of icterus a fortuitous infectious disposition. The presence of spirochetes in the liver could not be demonstrated at necropsy, although the spirochete seems to have a great affinity for the liver in heredosyphilis, thus causing the death of the infant but never of the adult. In fact, nonsyphilitic patients treated with arsphenamine likewise react with icterus, again proving the reactivation of the liver by arsenic. Graffar's patients even showed a certain proportion of arsenic in their hair, nails and blood. They also showed an increased urinary elimination of hippuric and of glycuronic acid. The icterus appeared three or four months after the last treatment and in one case the serologic reaction became positive with the appearance of the icterus. The author supports the infectious theory of postarsphenamine icterus.

Marginal X-Ray Shadows in Respiratory Diseases—According to Mighori, the juxtaleural marginal shadows that show in the roentgenograms of the thorax of children who are suffering from pathologic conditions of the lung indicate lamellar pleurisy, which originates in an inflammatory reaction of the pleura to the pulmonary process. The shadows give the lung the appearance of being covered by a veil. Bilateral shadows indicate an inflammatory reaction of the contralateral pleura, consecutive to that on the pathologic side. The contralateral pleural reaction may evolve to suppurative thoracic polyserositis, especially in infants. Grave pleural reactions overshadow the pulmonary symptoms. The disease follows a grave evolution with respiratory and pericardial complications. The exploratory puncture fails to give exudates. The clinical picture of the condition is different from bronchopneumonia, pleuritis and pericarditis. The author found at necropsy of children who died from acute diseases of the respiratory tract that the pulmonary condition causes lamellar pleurisy on the side involved by the pathologic condition and sometimes also on the contralateral side. In these cases the contralateral lung is normal and entirely coated by a film of thick and sticky exudate, which shows pneumococci. An infant that gave thoracic roentgenograms with evident bilateral juxtaleural marginal shadows had a suppurative thoracic polyserositis of rapid evolution. The presence of the latter was verified at necropsy, during which small amounts of purulent exudate were found in the pleural cavity and the pericardium. The structures were coated with a layer of sticky exudate about the thickness of a finger. The pus from the pleura and pericardium

showed pneumococci. According to the author, intrapleural marginal shadows are neither normal nor related to the technique used in taking the roentgenogram. They do not appear in all cases. Their appearance depends on a special reaction of the pleura, which is common on the side involved by the pathologic process of the lung, rare on both sides and grave in children, especially in infants. If the pleural reaction takes place, the shadows will appear in the roentgenogram regardless of the technique used in taking it.

Vitamin C and Ketonemia in Man—Negri studied the action of vitamin C (1-cevitamic acid) on ketonemia of normal persons and of diabetic patients and also the action of adrenal extracts on ketonemia of normal persons. The studies were made on living persons and also in vitro. He states that daily intravenous injections of 100 mg. of vitamin C given to normal persons for five days induce a slight and transient increase of acetone and acetoacetic acid followed by lowering of the three ketonemic fractions (acetone, acetoacetic acid and oxybutyric acid) of physiologic ketonemia. The same results are verified by following the ketonemic curves of normal persons every hour after administration of the injection. Daily intravenous injections of the same doses of the vitamin given to diabetic patients for five days induce in all cases an increase of the acetone and of the acetoacetic acid and a transient decrease of the oxybutyric acid. Daily intravenous injections of 75 biologic units of adrenal cortex extract without epinephrine given to normal persons for five days lower acetone and increase oxybutyric acid. Experiments in vitro gave the following results. Vitamin C (25 mg.) added to normal blood induced ketolysis of oxybutyric acid. Acetone could not be determined in the specimens of blood after the time necessary for obtaining the results of the experiments. The ketolytic action of the vitamin in vitro was the same in the blood of normal persons as in that of persons who had received intravenous injections of the vitamin. When the vitamin was added to hyperglycemic blood in vitro, it inhibited the ketolysis from dextrose.

 Magnesium Sulfate in Expectant Treatment of Eclampsia. G. Rossi—p. 231

Modification of Leukocytes in Syphilis—According to de Lillo, patients with recently acquired syphilis have hyperleukocytosis, increase of polynucleated neutrophils, decrease of the mononuclear leukocytes, especially the lymphocytes, and a deviation to the left of Arneith's formula. The patients are in the so-called nonspecific neutrophilic phase, which represents a condition of negative anergy of the organism due to inactivity of the lymphocyte system. Antisyphilitic treatment with mercury, arsphenamine or bismuth causes a diminution of the total amount of leukocytes and polynucleated neutrophils and an increase of the lymphocytes. The results are the same with any of the drugs mentioned. The patients enter the so-called active neutrophilic phase, which represents the fight of the organism against the infection, and then the lymphocytic phase, which indicates that recovery is taking place. Mercury, arsphenamine and bismuth have no direct action on the hematopoietic system. They act on the infection, the control of which results in regeneration of the organic defenses and in control of the disturbances of the blood. The author made determinations of the total amount of leukocytes, the leukocyte formula and Arneith's formula in a group of nine patients, in three subgroups, before and after administration of mercury, arsphenamine and bismuth. The results obtained with the drugs confirmed his statements.

Actinomycosis with Pyemia—Spangenberg and his collaborators state that actinomycosis as a rule is a local condition that may propagate through the blood when it is primarily located in the lungs and bronchi and cause metastases and pyemia. It is difficult to diagnose because the symptoms are those of pulmonary tuberculosis or, in some cases, of cancer or of syphilis of the lung. It is confirmed by the presence of the fungi in the cultures of the sputum, or, if the latter is not available, of those made with the material of one of the abscesses taken by puncture. Actinomycosis of the bronchopulmonary type follows a long evolution and the patient becomes cachectic. The disease generally begins as a chronic bronchitis or pneumonia and the lung becomes the seat of sclerosis or softening processes. In the case reported by the authors the diagnosis was made by identifying the fungi in cultures prepared with the material of a thyroidal abscess and verified at necropsy when multiple abscesses of the lungs, liver, spleen, kidney and thyroids, chronic pneumonia, parenchymatous peribronchial pulmonary sclerosis, passive congestion in one lung and putrid abscess in the other, dilatation of the right cavities of the heart, bilateral glomerulonephritis and amyloid degeneration of the kidney were found. The histologic study of the organs involved in the infection confirmed the diagnosis of actinomycosis of the bronchopulmonary type.

 *Cerebral Leukotomy Technic A Mattos Pimenta—p 47

Technic of Cerebral Leukotomy—Mattos Pimenta defines Munz's cerebral leukotomy as the section of pathologically fixed nerve fibers of white matter of the oval center made at the frontal lobe by means of a leukotome. The leukotome is an instrument made up of a metallic cannula 11 cm long and 3 mm in external diameter and graduated in centimeters. It is provided with a cutting loop 1 mm in diameter at the distal closed rounded end of the instrument. The cutting loop is enclosed in the cannula and comes out by certain movements of rotation at the proximal opened end of the instrument. Cerebral leukotomy is indicated in cases of functional psychosis which seem to be due to fixity of the cellular connections. The patient is prepared as for a minor operation, and the operation is done under local infiltration anesthesia with a 1 per cent solution of procaine hydrochloride. An oblique incision of 3.5 cm is made. The center of the incision corresponds to a point 3 cm down the middle line and 3 cm forward of an imaginary line perpendicular to the mean plane which joins the two tragi auriculari. A trephining orifice, 1 cm in diameter, is made on each side at the central points of the incision. An incision of 0.5 cm is made through the dura mater, so as to avoid injuring the vessels. The leukotome is gently introduced, with the cutting loop enclosed in the cannula, down to the frontal lobe, and the fixed fibers are sectioned. This has to be done in the absence of blood and cerebrospinal fluid. If any blood or cerebrospinal fluid is present the cutting loop is newly enclosed in the cannula and the latter gently removed and introduced in a new position. Sectioning of the nerve fibers is done at each frontal lobe with the instrument introduced to a depth of 3 or 4 cm. From one to four sections (two internal and two external) can be made at each frontal lobe. The wound is closed by suturing the

superficial planes with silk. The treatment is an attempt to cure psychoses. It has no contraindications. The author resorted to the operation in four cases (schizophrenia and psychoses of anxiety). The treatment failed in one case and caused immediate transient improvement in two and late permanent improvement in one.

Herpes Zoster of Epiglottitis—According to Franchini, herpes zoster of the larynx is rare. It develops in adults ranging in age from 20 to 50 years. The etiology of the disease presents many unsolved problems. The disease begins with the character of acute grip and evolves to a condition of acute neuralgia associated with painful dysphagia, a local burning sensation and appearance of the eruption, which follows the course of the superior laryngeal nerve, as a rule unilaterally and in exceptionally rare cases bilaterally. The differential diagnosis is made with herpes of febrile diseases, herpetic angina, chronic or recurrent buccal herpes, aphthous stomatitis and laryngeal papulous syphilitic erosion, syphilitic gumma and tuberculosis. The location of herpes zoster at the superior laryngeal nerve causes predominant symptoms of the epiglottitis. The treatment consists of administering drugs to combat the infection and the toxic condition, to stimulate the organic defenses and to soothe the tissues. To relieve painful deglutition, it is advisable to give an insufflation of a powder containing morphine, amylcaine hydrochloride B P, orthoform or dermatol five minutes before meals. Intravenous injections of urotropine preparations, autohemotherapy and injections of sodium hyposulfate give satisfactory results.

 *Metabolic Studies in Osteodystrophia Fibrosa Generalisata Before and After Extirpation of an Adenoma of Parathyroids W Brunner—p 330

Percutaneous Method of Arteriography of Brain—Shimidzu says that in 1932 he discontinued the exposure of the carotid artery and resorted to simple percutaneous puncture of the artery. The position of the head is important. It should be bent far backward so that the carotid artery becomes taut and does not escape the needle. The artery is punctured with a needle that is 0.8 cm in length and 0.9 mm in diameter. Anesthesia is generally unnecessary, but if the patient is nervous a local anesthetic may be applied. The site of puncture is the lower portion of the trigonum caroticum, within the sternocleidomastoid muscle, where the pulsation of the carotid artery can be felt best. From 5 to 6 cc of the contrast medium is injected in three or four seconds and the exposure is made immediately afterward. The author asserts that percutaneous arteriography is not only simple but also entirely without danger. It is helpful in the diagnosis of cerebral tumors and makes unnecessary the often dangerous encephalography. Arteriography permits a differentiation of the type of tumor. In case of a slowly growing tumor the involved vessel has a tendency to become thicker, whereas in case of a rapidly infiltrating tumor the involved vessel has a tendency to contract. Intracapsular and suprasellar tumors of the hypophysis can be differentiated on the basis of the connection of the sella with the vessels. For tumors of the frontal region the fronto-occipital exposure is important, and for tumors of the posterior cranial fossa arteriography of the vertebral artery is helpful. The author concludes that arteriography is advisable whenever the diagnosis of cerebral disorders proves difficult.

Metabolism in Generalized Fibrous Osteodystrophy—Brunner reports the history of a woman, now 45, who had generalized fibrous osteodystrophy. At the onset, twenty-two years ago, the disorder was diagnosed as multiple tuberculosis of the bones and shortly after as giant cell sarcoma, originating in the bone marrow. Surgery and roentgenotherapy were employed, the latter resulting in numerous relapsing roentgen ulcers of the skin. Examinations in 1935 and 1936 revealed chronic, severe osteoporosis with honeycombed vesiculated spongy substance, transformed and stringy compact substance, secondary cyst formations and sclerotic processes in the medullary space and the formation of fish vertebra. Hypercalcemia was accompanied by hypophosphatemia, the potassium and calcium contents of the blood were both increased, the blood chlorides were in the upper limits of the normal values and there were slight fluctuations in the mineral salts. The maximal fluctuation in the diurnal calcium curve was 0.2 mg per hundred cubic centimeters. The calcium content of the cerebrospinal fluid was normal as an indication that in the blood those calcium fractions are increased, which are not in solution equilibrium with the calcium of the cerebrospinal fluid, that is, particularly the complex calcium salts. An intravenous calcium tolerance test revealed a paradoxical calcemic reaction (reduction instead of increase of calcium content of blood). There was considerable calcium retention in the tissues. The metabolism tended toward the acidotic side. There was a slight disturbance in the intermediate fat metabolism and in the regulation of the carbohydrate metabolism. There also existed a mild form of adiposogenital dystrophy with a tendency to amenorrhea. A parathyroid adenoma was removed. Then chronic tetany developed gradually, but it responded to treatment with a viosterol preparation. The hyperparathyroidism was completely cured and the intermediate carbohydrate metabolism became normalized owing to the abolishment of the restricting influence exerted by the hyperparathyroidism on the sympathico-adrenal system. However, in spite of the complete cure of the hyperparathyroidism, the bone disorder, which had existed for twenty-two years, was not noticeably improved. The author emphasizes that deficient utilization of the calcium, which is caused by the hyperparathyroidism, plays a more important part in the genesis of the bone disease than does the abnormal increase in calcium elimination in the urine. The disturbance does not have to manifest itself in a negative calcium balance.

Louping Ill in Human Subjects—Following a review of four cases of laboratory infections with louping ill, which were reported in 1934, Wiebel gives the detailed clinical history of a woman, aged 26, who, as technical assistant in a laboratory, had been working for several months with the louping ill virus, the cause of cerebral symptoms (ataxia) in sheep. The infection apparently took place after the woman had undergone a minor dental operation. An infection with the virus of louping ill was indicated not only by the symptomatology but by the fact that some of the mice subjected to intracerebral inoculation with the patient's serum died with characteristic symptoms. Moreover, the virus of louping ill was neutralized by the patient's serum. By comparing this case with those reported in the literature, a similarity in certain symptoms can be observed. The disorder begins with influenza-like symptoms: prostration, headaches, dizziness and fever. After the symptoms have completely developed, cerebral symptoms, such as stupor, vomiting and visual disturbances, predominate, there are also high fever, bradycardia and mild leukocytosis with neutrophilia, the cerebrospinal fluid often has an admixture of blood, and there is an increase in its pressure, protein content and cell count. Meningitic signs and disturbances in the speech and in the reflexes are less often found. The case reported differs from others of this type by the absence of bradycardia

and especially by the extremely severe and lasting ataxia. The ataxia is a further proof of infection with the virus of louping ill, for this symptom makes the disorder more like that in sheep, in which the cerebral symptoms always predominate. The author stresses the similarity between louping ill and epidemic poliomyelitis, particularly as to the dromedary type of fever curve and the invasion of the virus through the mucous membrane.

Posterior Pituitary Extracts as Cause of Rupture of Uterus—Junghans calls attention to the dangers of incorrect administration of extracts of the posterior pituitary during delivery. He observed four cases in which the administration of excessive doses during delivery resulted in rupture of the uterus. To avoid such mishaps one should obey the following rules in the administration of posterior pituitary: 1 The intravenous injection of posterior pituitary should never be resorted to during the period of dilatation and expulsion. 2 During the period of dilatation ecchols should be given only in small doses. 3 If in case of a relatively small birth canal the labor pains are weak, the administration of posterior pituitary is advisable only if a careful vaginal examination has proved that spontaneous delivery is possible. 4 The dose for injection should never exceed 3 Vogtlin units.

Discoloration of Hair After Permanent Wave—Siemens describes three cases in which greenish blue or greenish black discoloration of the hair occurred after a permanent wave. The clinical histories of the patients and experiments conducted by the author indicated that when the scalp has been treated with mercury preparations, the customary methods of permanent waving produce ugly, smoky gray to greenish black discoloration of the hair. In the reported cases, substances containing mercury had been applied because of psoriasis of the scalp. It was found that the discoloration develops even if the mercury preparation has been applied weeks or even months before and the hair has been thoroughly washed. Persons with blond hair particularly should be warned of this. The color reactions could be reproduced in vitro.

Examination of Collected Swab Specimens in Diphtheria Patients—Lenz maintains that the result of a single examination of the nasopharynx is not sufficient for a definite decision regarding the presence or absence of diphtheria bacilli. At the clinic with which the author is connected it has been the practice in the last two years to obtain a specimen for examination not once a day but rather at two hour intervals from 6 a. m. to 8 p. m. It was found that the examination of these "collected specimens" makes the bacteriologic diagnosis of diphtheria much more reliable. The specimens obtained in the morning produced from 40 to 50 per cent more positive results than did those taken during the afternoon and evening. The collected specimens proved valuable also in the recognition of diphtheria carriers, for the collected specimens of almost 30 per cent of carriers gave positive results when the examination of a single pharyngeal swab specimen had been negative. Finally, the collected specimens were used to determine the disinfecting action of lemon juice on diphtheria bacilli, for lemon juice is widely regarded as a pharyngeal disinfectant.

in cases of diphtheria. The equal number of positive results with and without the application of lemon juice demonstrated that lemon juice does not inhibit the growth of diphtheria bacilli.

Sedimentation Speed in Digestive Tract Tumor—Stengel studied the sedimentation speed of the erythrocytes in sixty patients with definitely demonstrated carcinoma of the digestive tract and in 120 patients with gastric ulcer or gastritis. He observed that in a large percentage (88 per cent) of cases of malignant tumor of the digestive tract the sedimentation speed is greatly increased. However since the sedimentation was normal in seven of the patients with carcinoma a normal rate of sedimentation is not a definite proof that malignant neoplasm is absent. In patients with ulcer, on the other hand, even if there is also gastritis, the sedimentation is generally not accelerated, for in only twelve of a total of 120 cases was there a considerable increase in the sedimentation speed, and in some of these cases the acceleration was the result of other inflammatory processes. The author concludes that if it is necessary to differentiate between ulcer and malignant neoplasm, the sedimentation test has some value.

- *Turning Syndrome of Frontal Brain. L. Halpern—p. 505

Hemophilia in Women—Bauer and Meller review the literature on hemophilia in female patients. They answer in the negative the question whether the hereditary rule, now generally accepted, applies to all cases of hemophilia. They think that there are families in which the hemophilic factor becomes manifest only in males, that occasionally there are families in which the men and the women show hemophilic symptoms, and that in rare instances only the women show hemophilic symptoms. They do not consider the time ripe for the formulation of definite laws of the hereditary transmission of hemophilia. To be sure, they concede that such frequent, severe and fatal hemorrhages as occur in hemophilic men are only rarely observed in women. After suggesting explanations for this phenomenon, they describe observations on four women whose disorder was characterized by a symptomatology similar to that of hemophilia as well as by a weakness of the thrombocytic apparatus. Whereas the first two cases described in this report lead the authors to reemphasize the definition of hemophilia in women, the latter four cases indicate that combinations of hemophilia and thrombopenia may occur and that it is not justified to draw sharp distinctions between these two disorders. The cases permit the assumption that the female sex organs provide a specific protection against fatal hemorrhages.

Irradiation of Spleen with Short Waves in Hemolytic Anemia—Groag relates the history of a woman with hemolytic icterus in whom he resorted to irradiation with short waves. He subjected the patient from five to six times each week to irradiations of the spleen. The irradiations were applied with a tube apparatus of about 250 watts, which produced waves 4 meters in length. After ten irradiations with short waves, the bilirubin content of the serum decreased considerably and so it was hoped that in the mild cases of hemolytic icterus the condenser field treatment of the spleen would be helpful at least as a symptomatic treatment at the time of the blood crises. The later examinations of the blood have made this doubtful, as far as this can be estimated on the basis of a single case. But the condenser field action on the spleen could perhaps serve another than a therapeutic purpose in hemolytic icterus. If in a larger material blood tests would be made throughout the duration of the irradiations, it might be possible to detect a certain regularity of the changes, which in turn would give an insight into the still unexplained connection between the excessive hormone production by the spleen and the temporary insufficiency of the bone marrow. Thus an explanation

might be found for the apparently unmotivated appearance of blood crises in hemolytic icterus.

Turning Syndrome of Frontal Brain—Halpern says that, in studies of patients with disease or injury of the frontal brain, he found that the disturbances in the equilibrium which appear are not uniform but that symptoms of two entirely different frontal brain syndromes are involved. One syndrome includes frontal disturbances of the equilibrium in the restricted meaning of the term, whereas the other, which is discussed here, originated in the precentral region, in the area agranularis frontalis in field six, and in the adjoining area frontalis intermedia in field eight, according to Brodmann. The disturbances that develop in case of lesions of these areas are essentially of three types: an epileptic spasm, disturbances in the turning of the head and in the innervation of the eyes, and certain disturbances in standing and walking. The author demonstrates that all these symptoms are based on a disturbance in the turning capacity of the organism and that this basic function is localized in the aforementioned area of the frontal brain. This area agranularis has, as is indicated in the term, no internal granular layer and in this respect it resembles more the adjoining motor zone than the other parts of the frontal brain. Moreover, it resembles the motor zone physiologically in that it is the only site in the frontal brain that responds with a motor movement to stimulation. This motor function is understandable when it is considered that this area controls the voluntary movement in an aimed direction.

Negative Insensible Perspiration—Frohlich and Zak point out that disturbances in the water exchange, as exist in case of insufficiency of the right side of the heart, may be accompanied by disorders in the elimination of water by insensible perspiration. Clinical and experimental observations convinced them that patients with severe chronic cardiac decompensation and some patients with obesity, under certain conditions show increases in body weight which are caused by negative insensible perspiration. These paradoxical conditions are not often demonstrable. In forty one tests on nineteen patients with severe chronic cardiac decompensation they were able to demonstrate negative insensible perspiration only twelve times. The patients were carefully watched and were weighed at intervals of from thirty to sixty minutes for periods of from five to seven hours. The authors cite corroborating and contradicting statements made by other investigators about negative insensible perspiration and suggest reasons why the latter arrived at contradictory results. They are of the opinion that, in patients whose tissues have a great avidity for water, moisture from the air may enter the body either through the skin or through the lungs. Studies on the penetration of moisture through the skin revealed that in cases in which this took place the moisture content of the air was unusually high. The authors describe their experimental studies on the capacity of the lung to regulate the water content of the blood. Tests were made on rabbits with moist oxygen and with dry oxygen. It was found that thickened blood is diluted in the lungs. Moist air in the lungs is a prerequisite for this diluting reaction. The lung takes the moisture (1) from the inspired air and (2) from the respiratory tract. After pointing out that the diluting action of the lung is a further proof of the possibility of a negative insensible perspiration, the authors discuss the significance of the diluting reaction of the lung.

Vitamins B₁ and B in Insulin Shock Therapy of Schizophrenia—Freudenberg shows that the dangers of insulin shock therapy in schizophrenia have been overestimated. The four fatalities that occurred in 250 cases (1.6 per cent) were partly caused by technical errors, which are not entirely avoidable in a new treatment. Greater experience and improvements in the technique have made it possible to reduce the dangers. The chief sources of danger in insulin therapy are

those rare conditions of shock which do not yield at once to oral or intravenous administration of sugar and which persist in spite of hyperglycemia or normoglycemia. Such conditions of shock generally develop only after several reversible shocks have preceded. The time of interruption likewise seems important for the development of these shock conditions, and it is therefore advisable to arrest a deep hypoglycemic coma at the latest after ninety minutes, or approximately five hours after the injection. At the suggestion of Pick, the author tried to influence the refractory conditions of shock by the administration of vitamins B₁ and B. In a number of patients, who did not wake up within thirty minutes after the oral administration of sugar solution and who previously had required intravenous injection of dextrose solution, the author resorted to the administration of vitamin B or of a yeast emulsion. In response to this, the patients woke up rapidly and did not require an intravenous dextrose injection. The author concludes that the administration of vitamin B is indicated at least in the aforementioned cases and says that experiments are now being made with the prophylactic application of vitamin B.

*Therapy of Migraine and of Other Allergic Disorders in Women by Means of Oxidation Ferments O Zajicek—p 486

Problem of Erect Body Posture E Klinghoffer—p 488

Therapy of Migraine in Women—Zajicek says that it has been proved in recent investigations that the combustion processes are retarded in patients with migraine. This not only proves that migraine is a metabolic disorder with retardation of the oxidation processes but that oxydase therapy is correct in cases of migraine and other conditions that are accompanied by a slowing down of the metabolism. Before reporting his observations on the oxydase treatment of forty-seven women with migraine, the author discusses the theoretic foundations of this treatment by means of oxidation ferments. He used oxidation ferments from the testes and epididymes of young steers, because it had been proved that these products facilitate the respiration of the tissues and that they cause an increase in the osmotic pressure and by this in the activity of all tissues, but particularly of the heart and the circulation. It was detected also that the extracts of the testes accelerate the oxidation of the waste products, promote assimilation and prevent the accumulation of noxious substances in the tissues. The oxidation ferments from testis and epididymis were given either in the fresh form or in the form of powder combined with vegetable ferments. Of the forty-seven women with migraine who were subjected to this treatment, forty-five responded promptly, the headaches subsided in many cases after the second or third dose. In the patients who also had constipation, the intestinal function was normalized although all purgatives had been discontinued. At the onset of the ferment therapy, all administration of analgesics was discontinued and the patients were put on a meatless diet until the headaches subsided. The favorable results obtained in cases of migraine induced the author to resort to the treatment with oxydase powder for other allergic conditions. He demonstrates the favorable effects on such conditions in one case each of severe asthma, urticaria and brachial paralysis in case of cold allergy.

Influence of Electrolytes on Chronaxy of Vestibular Nerve—After prolonged experimentation on rabbits, Hurynowiczowna and Rubinsztejn came to the following conclusions: 1 Calcium salts injected intravenously with the object of increasing the amount of calcium in the blood clearly decrease the chronaxy of the vestibular nerve. 2 Sodium ovalate injected intravenously with the object of decreasing the calcium in the blood increases the chronaxy of the vestibular nerve. 3 Magnesium salts injected intravenously increase the chronaxy of the vestibular nerve and have an antagonistic action toward

calcium salts, in analogy to the known antagonism of magnesium toward calcium, in their action on the nervous system. 4 The modification in the chronaxy of the vestibular nerve after the introduction of the electrolytes changes back to normal in a fairly short time, generally after two hours and at times in one hour. 5 The changes in chronaxy produced by the electrolytes have been different for the different vestibular nerve reactions, this difference has been especially marked after the injection of magnesium sulfate.

Action of Arsenic on Nails—Simons directs attention to the fact that in arsenic poisoning, particularly in arsenical polyneuritis, the appearance of diagonal white stripes, the so-called Mees's stripes, on the nails is a characteristic sign. Not only are these stripes helpful for the diagnosis, but by taking into consideration the average rate of growth of the nails it is possible also to determine the time when the poisoning took place. After reviewing the literature on leukonychia striata transversa arsenicalis, the author reports two cases. The first patient, a man, aged 32, had psoriasis with ungual and subungual hyperkeratosis. The ungual psoriasis responded to treatment with arsenic and it proved possible to determine the beginning, the duration and the course of the action of the arsenic. Two months elapsed before the effect of arsenic medication became apparent on the nails. The second patient had arsenical polyneuritis. From the diagonal white stripes on his nails it was computed that the acute arsenic poisoning must have taken place six months before. Although chronic exposure had begun two and a half years earlier, when the patient first took up his hobby of stuffing birds (using arsenic), the white stripes on the nails indicated that an acute poisoning had taken place only six months before. The anamnesis revealed that at that time the patient had stuffed a rather large animal, a wolf, on which occasion a far greater amount of arsenic had to be used and must have been ingested.

*Effect of Epinephrine on Blood Pressure and on Addison's Disease C Grill—p 628

Effect of Epinephrine on Blood Pressure—Grill describes a case of Addison's disease in which he tried treatment by means of the intravenous injection of epinephrine. It was found that the epinephrine increased the patient's blood pressure from 75 mm of mercury systolic and 50 diastolic to 120 systolic and 80 diastolic and kept it at this level for about forty hours. However, there was no perceptible improvement in the patient's general condition. After the administration of epinephrine was stopped, the blood pressure fell again, there was a marked decline in the general condition and the patient died. The postmortem examination revealed complete destruction of both adrenals by caseous tuberculosis. The author further discusses the epinephrine requirements. On the basis of earlier observations and experiments, he reaches the conclusion that the effect of a certain dose of epinephrine is not the same at different levels of blood pressure either in the same or in different persons. In the case of extremely low blood pressure, the effect of the administration of epinephrine is usually slight. Epinephrine is most effective in the case of normal blood pressure. At higher levels of blood pressure the effect of epinephrine becomes increasingly poorer.

FACTORS INVOLVED IN SATIS- FACTORY SHAVING

LESTER HOLLANDER, M D

Chief Dermatological Service Pittsburgh City Hospital Chief,
Dermatological Service Montefiore Hospital Medical Director
Pittsburgh Skin and Cancer Foundation

AND

ELBRIDGE J CASSEMAN, S B

Industrial Fellow Mellon Institute University of Pittsburgh
PITTSBURGH

This article is a summary of the results of four years of investigation on the subject of shaving conducted at Mellon Institute. Our purpose in the study was to ascertain the factors that are involved in obtaining a satisfactory shave, to learn their relative importance and to find such additional information, either in the preparation of the face or in the design of razors, that would lead to improvement in the technique of this daily task.

It is said that it was Scipio the younger¹ who introduced shaving as a daily procedure among the Romans. But of course pogonotomy,² or shaving, is a much older art. Archeological excavations have uncovered objects in most ancient civilizations, including Egypt and Babylonia,³ which today are regarded as razors. The Bible⁴ contains decrees regarding shaving. Barbers were a distinct group of artisans as early as 400 B C in Greece.⁵

Despite the established antiquity of shaving, little reliable information of pertinently technical nature can be found. There have been expressions about the hygienic phases of shaving coming from both medical⁶ and lay⁷ writers. Certain aspects of shaving have also received special attention, such as the effects of soaps and soap constituents on the skin,⁸ the effects of

water,⁹ of detergents,¹⁰ and of other liquids¹¹ in softening the keratin of hair, the effects of repeated cutting and shaving on the hairshaft itself,¹² the variation in the angle which the emergence of the hairshaft forms with the skin,¹³ the variations in skin sensitivity,¹⁴ and the variations in the quality and quantity of sebum secretion.¹⁵ General instructions for shaving have been given occasionally.¹⁶

An extensive search of the literature, however, has not revealed a single or recent publication which integrates the various aspects of this subject. It is to meet this need particularly that this article has been prepared. In it we are going to deal with the softening of the hair in preparation for shaving, with the effects of shaving on the skin and with the technique of controlling these aspects of shaving.

EXPERIMENTAL METHODS

A shaving clinic was established at Mellon Institute in 1931. It consisted at various times of from ten to fifteen experimental shavers who, being scientists, were unusually well qualified to follow directions meticulously and to observe effects accurately. All these men were employees of Mellon Institute. They shaved under the direction of one of us (E J C) daily.

The entire group consisted of thirty-one men of whom twenty were blond and eleven brunet. Of the twenty blonds, five had unusually coarse beard hair with an especially thick growth, the same was true of six of the eleven brunets. Of the blonds, nine had rather light beards, the same was true of three of the brunets. Sensitiveness to the discomfort of shaving

with dull blades was not confined to those having dense beards but included some of those having light beards as well. Included in the group were nine who shaved daily during one year, five who shaved daily during two years, eight who shaved daily during three years or more, and nine who shaved at irregular times.

The time required to soften hair by aqueous solutions was studied by measuring the rate of elongation of the hair when stressed with 16 Kg per square millimeter of load, being immersed in a test liquid. This amount of load does not stretch hair appreciably in its dry state, but when the hair is fully saturated with water it produces a stretch up to 50 per cent of its original length.¹⁶

For this test 25 cm (10 inch) long scalp hairs were used having a diameter of from 0.055 to 0.063 mm (from 0.0022 to 0.0025 inch). The amount of stretch was measured during time intervals up to one-half hour.

To measure the quantity of hair and skin removed by shaving, the accumulated material was washed from the razor with a lather solvent (1 part of ethylene

Fig 1—Angle measurements (diagrammatic only, not to scale)

dichloride and $1\frac{1}{2}$ parts of ethyl alcohol), rinsed by decantation with the same solvent and then centrifuged, graduated centrifuge tubes being used. Under these conditions the line of demarcation between the compacted hair chips (lower layer) and the compacted skin particles (upper layer) was quite sharp.

In respect to evaluating the design of different types of safety razors, our experiments showed that the knowledge of an angle, which is called the "effective shaving angle," is the item of prime importance.

This angle was ascertained by taking the measurements of the angle formed between the central plane of the blade near its edge and a plane which passes through the edge and is tangent to the guard bar. In some cases corrections were found to be necessary, as follows: the addition of from 2 to 3 degrees when the guard is composed of teeth instead of being a solid bar, the addition of from 1 to 2 degrees when the distance from the blade edge to the tangent point is in excess of 1.40 mm (0.055 inch) by from 0.38 to 0.75 mm, the subtraction of from 1 to 2 degrees when this distance is under 0.11 mm. The method is illustrated in figure 1, which represents the portions of a safety razor that are actively useful in shaving. Here the angle AOB is the angle that is measured, and the dimension OC is the distance on which the angle corrections are based.

Examination of the freshly shaved skin was made by means of a standard textile "pick counter," in which the handle contained a small flashlight for giving the surface slantwise illumination. The lens magnification was approximately 11.

Other observations were made by the "patients" of the shaving clinic, who, under various conditions (types of safety razors, various soaps or brushless creams), reported their own reactions to the following aspects:

- 1 The relative amount of effort required to obtain a clean shave
- 2 The relative discomfort associated with "pulling" effects during the passage of the razor
- 3 The relative amount of stinging following the use of an after-shaving lotion containing 50 per cent ethyl alcohol
- 4 Other miscellaneous and pertinent information

The director of the clinic (E J C) kept detailed information regarding (1) the kind of soap used in both preparation and shaving, (2) the water temperature, (3) the time consumed for preshave facial preparation, (4) the effective shaving angle of the razor, (5) nondestructive tests of the initial and final sharpness of the blade by means of an instrument designed for this purpose,¹⁷ (6) razor blade hardness, brittleness in bending, composition, metallographic structure, and the like, (7) razor edge conformation, (8) degree and character of the injury sustained by the shavers, and (9) a general record of the individual characteristics of the "patients", i. e., average diameter of the hair, density of spacing, and the average angle between the hairshafts and the skin.

In many cases the conclusions that were indicated by the tests were checked by means of a "comparison shave" method in which two items would be compared in the same shave. For example, for comparing the reactions to dull and sharp blades, identical razors would be loaded with a sample of each, and then the two compared in a single shave.

Experience showed that the time of shaving should be divided for study into two intervals: (1) preparational period, during which the major softening of the hair took place, (2) shaving period, during which the razor was used.

OBSERVATIONS

1 Generalities—The skin and its appendage, the hair of the face, are subjected to a number of normal influences having direct effects on the problem of shaving. Externally these influences are exposure to weather, wind, solar radiation and the effects of shaving, which include facial preparation, trauma of the passage of the razor over the skin, and the after-shaving toilet. Internally one has to consider such things as diet, the excretory mechanism of sweat and sebum, growth and replacement of epidermis and hairshaft, and the circulatory mechanism of the true skin.

There are two types of hairshafts covering the face: hairshafts belonging to the finer class—the lanugo hairs, whose diameter is considerably less than 0.025 mm, and the coarser hair, whose diameter runs from 0.091 to 0.230 mm. It is the latter class that concerns us in shaving. The measurements given agree with those of other writers.¹⁸

The distribution of the coarse hairs varies not only with the individual but also with the location on the face as will be shown later (table 5).

These data agree definitely with the observation that the greatest difficulty is encountered on the upper lip and on the central portion of the chin.

The rate of growth of hair is fastest immediately after shaving, then it becomes slower until a normal average of from 11 to 12 mm a month is attained.

17 Casselman E. J. U. S. patent 1983597
18 Danforth L. Fuchs L. Seymour L.

This normal rate is not affected by shaving or cutting. Neither is the thickness affected by either process.¹⁹

Hair on the face never grows out perpendicularly, except occasionally on the curvature of the chin anteriorly. The actual angle between the hairshaft and the epidermis varies with individuals and also with the various portions of the face of the same subject. The range is ordinarily from 31 to 59 degrees,²⁰ except near the anterior cervical triangle, where the hair may grow out nearly flat or lie in a furrow.

TABLE 1—Relation Between Time of Immersion and Stretch of Single Loaded Hairs

Condition	Fraction of Full Stretch Observed					
	20 Sec	40 Sec	60 Sec	80 Sec	100 Sec	150 Sec
Tests with plain water						
Dark hair 120 F	0.70	0.56				
White hair 120 F	0.70	0.56				
Dark hair 56 F	0.55	0.54	0.90			
White hair 54 F	0.10	0.30	0.60	0.82	0.93

Tests with saturated soap solution at 75 F						
Dark hair	0.50	0.90				
Dark hair	0.38	0.82	0.92			
White hair	0.11	0.51	0.80	0.90		
White hair	0.09	0.40	0.77	0.91		
White hair	0.08	0.33	0.67	0.87		

There are a few points in regard to the skin of the face that are of interest here. Thickness of the stratum corneum of the face varies between 0.0067 and 0.033 mm. The thickness of the epidermis, including the stratum corneum, varies between 0.2 and 0.3 mm. The thickness of the cutis vera varies between 3.5 and 4.6 mm.²¹

The true cause of ingrowing hairs is not known except in keratosis pilaris, but slanting wounds through the corium above the hair root²² and also traumas of the skin surrounding the hair shafts^{10c} seem to have a predisposing action. Some writers have erroneously ascribed such traumas to "dull razors."^{13e} Our experience indicates that, in respect to safety razors, trauma occurs less with dull blades than with sharp ones.

The skin surface is furrowed and wrinkled. We found that a very slight stretching of the skin was sufficient to make the surface essentially smooth, more severe stretching caused the disappearance of deep wrinkles, still more severe stretching, especially over the bony parts of the face, resulted in the protrusion of the skin at the site of the hair follicles, giving the appearance of gooseflesh (cutis anserina). Thus one can readily appreciate that severe stretching may cause a man to cut himself while shaving, because the protrusion mentioned causes an unevenness of the skin surface.

In some cases the skin forms a deep pit or depression around the emergence of the hair shafts. These deep pits interfere materially with obtaining a close shave.

2 Hair Softening—Composition and Reactions to Water. The chemical composition of hair has been shown to be chiefly keratin, a highly complex organic material containing nitrogen and sulfur. Sulfur occurs in the form of cystine, of which human hair contains more than does that of other animals. The stratum corneum also consists mainly of keratin. Keratin is insoluble in water, but it absorbs water readily. It is

completely soluble in strong alkalis. The tensile strength and consequently the hardness of hair are lessened by water absorption.^{2a}

Hair also takes up sebaceous secretion, which retards water absorption—an important factor in shaving, because in hair covered with sebaceous secretion there is a delay in water absorption during lathering.

The primary purpose in preparing the face for shaving is to modify the initial hard condition of the hairshaft. Secondary purposes are the lubrication of the razor blade, provision of a stiff supporting medium for the hairshaft, the protection of the skin from trauma, and the antiseptic action of soaps. Our experience leads us to believe that those purposes classed as secondary are of minor importance. Dull blades incompletely softened hairs or improper shaving angles are the main causes of unsatisfactory shaving.

The preparational period is concerned largely with the softening of the hair prior to shaving.

The time requirement was studied in the case of single hairs by means of the tests on stretching hairs as immersed under loads in liquids. Typical examples of tests showing the relation between fraction of full stretch and time are given in table 1.

These tests indicate the great importance of the temperature of the liquid in governing the length of time that elapses before stretching the hair is practically complete. They also indicate the value of soap solution as compared with plain water and the slower softening rate that occurs in the case of gray or white hair.

It may be assumed that facial hair is substantially softened under the same conditions that produce 0.85 of its full stretch under load. Table 1 shows that for scalp hair, when water at 120 F is used, the time requirement is from forty to forty-five seconds. We multiply by 4 to correct for the difference in the cross-sectional area in beard and scalp hairs, which gives the minimum time of from two and one-half minutes to three minutes. This minimum preparational time would be increased with the use of colder water, particularly in the case of gray or white hair.

TABLE 2—Average Service Life of Razor Blades as Affected by Duration of Facial Preparation

Preparation Time Minutes	Average Number of Full Shaves
0 dry	Under 1*
1/4	20
3	40
10 (shower bath)	50

* Both the pulling effect and the stinging sensation after the shave were very painful.

Duration of Preparation in Actual Shaving The effects of time of preparation in actual shaving were studied by measurements of the dulling of standard razor blades and were corroborated by reports of discomfort by the shavers.

The results of the tests for the dulling of razor blades are presented in table 2 in terms of the average service life.

The reports on the discomfort of shaving reached a minimum with all types of razors and blades when preparation was extended to three minutes or longer.

These results all indicate definitely that not less than three minutes' preparation is required to soften the hair for the most satisfactory shaving conditions.

3 Soaps and Latherless Shaving Creams—After many trials and errors, civilized men at present prefer soap solutions as hair-softening mediums. The chief reason for this preference lies in the fact that soaps

19 Seymour¹² Bulliard¹² Trotter¹²

emulsify the waterproof sebum covering the hairshaft. This emulsification enhances the wetting of the hairshaft.

Irrespective of the fact that the length of the hairshaft after twenty-four hours' growth is but one-fiftieth inch (0.5 mm), most men feel better pleased with their shaving when the lather is half an inch deep on their faces. Such lather can be produced only by the use of a soap specially prepared for shaving and a shaving brush.

Desirable properties of shaving soaps are voluminous lathering quality, resistance to rapid drying on the skin, freedom from the possibility of causing skin irritation, and tendency to prevent delay in the softening of the hair by the water in the lather.

As is well known to soap technologists, the first three properties are mainly dependent on the chemical composition of the soap, with respect to both the type of alkali used and the type of fatty oil or acid combined with it.²³ In respect to the fourth characteristic, it is our experience that the composition of the soap has

Fig. 2—Centrifuge tubes containing both hair (lower layer) and skin (upper layer) removed in shaving by different persons

little bearing on its effectiveness as a beard-softening agent so long as it has emulsifying properties and meets the limitation that it should not irritate the skin. The best shaving soap devised does not compensate for the use of cold water or for a dull blade. On the other hand, the use of hot water, a preparational time of from two and one-half to three minutes and a sharp blade in a correctly designed razor make the use of any nonirritating soap perfectly satisfactory whether a brush is used for lathering or not.

The beard can also be softened by the special preparations marketed as latherless shaving creams. These mixtures have a wide variety of composition, but for the most part they consist of from 15 to 25 per cent stearic acid, from 5 to 7 per cent glycerol, hydrous wool fat or liquid petrolatum, from 1 to 2 per cent alkaline emulsifying agent, and from 60 to 70 per cent water. Waxes and perfumes are also added in small quantity. Some of them contain small quantities of a wetting agent, such as sodium lauryl sulfate. We have found that the softening action of these preparations when

used alone is slower than that of soaps. The stiffer brands tend to clog the razor more than does soap.

Shaving soaps are usually manufactured to have a p_H of from 8.5 to 9.5. The latherless creams often have a p_H of less than 7.0. The use of either type is unlikely to result in skin irritation such as is caused by strong alkalis. Hand soaps that contain "builders" to counteract the constituents in "hard water" may carry excessive alkali and should be avoided both for preparation and for shaving. If there is a suspicion that one is allergic to constituents of some brand of soap, such a brand should not be used.

We have learned, as have others,²⁴ that the latherless creams tend to cause a decrease in the apparent durability of razor blades, owing no doubt to the p_H value of these creams. In our tests this decrease could be counteracted by mixing soap with the brushless cream on the face, which mixture has essentially the same p_H as pure soap solution.

The practice of some persons of mixing petrolatum with shaving soap results solely in a tendency to stiffen the lather. Stiff lathers tend to protect the skin from trauma by preventing the closest possible shave.

4. Safety Razors—Purpose and General Characteristics. The purpose of all razors, including safety razors, is to provide an instrument by which the growth of hair can be planed off even with the skin. Although the first safety guard was fitted to a razor in 1875,²⁵ the guarded safety razor did not come into common use until the twentieth century. At present it is probable that well over half the adult males in the United States use safety razors for daily shaving.

The original purpose of the safety razor was the addition of a safety factor in the form of a guard to the blade, so that the amount of skill required to shave without cutting the skin would be diminished to the point at which relatively unskilled hands could accomplish it. This safety feature usually results in freedom from gross trauma of the skin.

Except for items of weight, balance, convenience of operation and other features that appeal to personal preferences, safety razors differ in shaving quality largely as a result of their differences in the effective shaving angle.

Mechanics of Shaving. The shaving of a hairshaft having a growth of from 0.5 to 1 mm above the surrounding skin surface is similar to any planing operation. There are a number of complications, however, that enter into the picture. One is that the hair is set in a yielding rather than in a rigid base, thus when the razor blade is forced against the hairshaft there is a tendency to deflect the latter about its root (not at its point of emergence from the skin) as a center, to a position in which it makes an even smaller angle with the skin than it normally does. The result is that, when the hair is shaved off, a somewhat pointed stub remains, and the impression is gained that the shave is not close or clean. The duller the blade, the more conspicuous is this effect.

Likewise the smaller the angle that the hairshaft makes with the skin, the more difficult it is to get a close shave the first time the blade passes over the skin. Some men can never get a close shave on the first passage of the razor because of the combination of an unusually small hair-skin angle and an unusually yield-

²⁴ Fash, R. H. Increasing the Effective Life of Razor Blades. *J. Indust. & Engin. Chem.* 29: 68-70, 1937.
²⁵ Cutlery in New Standard Encyclopedia. New York: Funk & Wagnalls, 8: 266, 1931.

ing character of the skin. This difficulty can be surmounted only by shaving against the grain, that is, against the direction of the hair growth, or by the use of an increased angle between the blade and the skin, or by a dangerous overstretching of the skin to increase its rigidity. It is the guard bar of a safety razor that in reality should function as the stretcher of the skin.

Another complication is the thin dimension common to all types of razor edges. Such edges are subject to localized deflection during shaving, which operates locally at each hairshaft to increase the angle between the blade and the skin.

Like other planing tools, a razor blade should be used with a definite clearance angle between the trailing face of the blade and the freshly cut surface of the hair. This angle should obviously be small enough to prevent the planing off of the stratum corneum as well as the hair. The clearance angle of a razor blade in a safety razor naturally differs from the effective shaving angle by a constant amount. Because the latter is easily measured, we have used the effective shaving angle rather than the clearance angle in our shaving experiments.

Effect of Shaving Angle. Experimentation was conducted on rods one-half inch in diameter made from plasticine to simulate softened hair on a magnified scale. It was concluded that the greater the clearance angle, the shorter would be the point of the stub, corresponding to a closer shave in practice, but greater forces were necessary with the larger clearance angles, corresponding to greater "pulling" discomfort during actual shaving.

These observations indicate that the best effective shaving angle is a compromise between conflicting items of shaving satisfaction, and that this compromise may not lie at the same point for all persons. In actual shaving practice, increasing this angle always resulted in an increase in the discomfort felt during shaving, in an increase in the depth of minor excisions of horny layer surrounding the hairshafts, and in a lessening of the effort required to get a close shave. The minimum amount of injury to the skin was found with effective shaving angles at 25 degrees and less. Razors having such angles might have special applications in unusual cases of extremely sensitive skin, but angles of from 28 to 32 degrees give many men a better combination of freedom from discomfort during shaving, ease of close shaving and minimum damage to the skin.

5 Razor Blades and Blade Edge Durability.—A study of safety razor blades showed that practically all of them are made from steel as good for shaving purposes as the best steel ever used for an old style straight razor, if not better. As a matter of fact, the quality of the steel, except in the newer alloy steels, has little bearing on its value as a razor within the range of quality from which the manufacture of razor blades is attempted. The quality of the steel is of much greater importance to the blade manufacturer in affecting the ease with which he can sharpen it properly.

We studied the durability of razor edges, which subject will be covered in other publications, but there is one item of interest to the medical profession because of its possible bearing on the surgeon's scalpel. The conformation of the edge was the most important single quality affecting its durability. The most durable edges were those in which all serrations were removed that were visible in profile with a 4 mm., 0.85 numerical aperture objective, by proper stropping with canvas

and leather. Such edges also tended to have the best sharpness in the absence of overstropping.

Corrosion of the edge, either during shaving or while the blade was stored between shaves, was a very minor factor in the whole mechanism of edge failure.

The automatic sharpening equipment of the more experienced blade manufacturers produces sharper blades than do any of the devices that are sold for resharpening used blades. Many of these devices, however, will resharpen an unserviceable blade to the extent that it is again useful.

6 Effort Required to Obtain a Close Shave.—The effort required to obtain a close shave was judged from the number of passages of the razor required or from the amount of pressure or "digging" needed during shaving. Our observation on these points can be summarized as follows. The effort needed increased (1) as the effective shaving angle decreased, (2) as the blade became dull, (3) if the preparational period was inadequate, and (4) as the stiffness of lather was increased, or if it clogged the razor. The effort decreased (1) if the skin was stretched enough to smooth the wrinkles and to raise the level of the pits, (2) with dull blades

Fig 3—Chips of hair and skin removed in shaving (slightly reduced from a photomicrograph with a magnification of 35 diameters). Note excised skin particle in center.

when a diagonal or slanting stroke of the razor was used, and (3) if the razor stroke was made against the direction of the hair growth or "grain."

Of these items, blade sharpness and effective shaving angle were the most important in their bearing on the effort required to obtain a close shave.

7 Discomfort During Shaving.—Discomfort during shaving is usually associated with a "pulling" effect. This effect increased (1) as the blade became dull from use or was otherwise insufficiently sharp, (2) if the preparational period was inadequate to soften the hair fully, (3) as the effective shaving angle was increased. (Discomfort was practically absent at from 20 to 25 degrees and was conspicuous over 40 degrees.)

Discomfort decreased when a slanting or diagonal stroke was used. Complaints of discomfort were more frequent from men having coarse, densely spaced hairs. For such men the effects of blade sharpness and duration of preparation were important items in controlling the comfort of shaving.

8 Effects of Shaving on the Skin.—Shaving with both safety and knife type razors was found to remove small quantities of skin along with the hair. Figure 2

shows the manner in which the quantities were measured, while figure 3 illustrates samples of the chips of skin and hair removed

Tables 3 and 4 record typical examples of the measurements

Extreme differences in the quantity of skin and hair removed occurred in different men in the proportion of 4 to 1. Differences in the same person were not

TABLE 3—*The Average Quantity of Skin and Hair Removed in Shaving Each Twenty-Four Hours by Different Persons*

Individual Shaver, Number	Quantity in Cc	
	Skin	Hair
1	0 50	0 63
2	0 32	0 60
3	0 30	0 30
4	0 30	0 29
5	0 19	0 29
6	0 30	0 21
7	0 15	0 30
8	0 13	0 23
9	0 17	0 20
10	0 17	0 17
11	0 25	0 10
12	0 12	0 14

great in the amount of hair removed each twenty-four hours, while the difference in the amount of skin removed varied to a greater extent

Examination of the freshly shaved skin led to the observation that trauma of the skin consisted principally in the excision of the horny layer of the epidermis, such damage occurred mostly at the follicular hairshaft openings. This localized traumatism increased in proportion to all the factors that tend to promote a close shave, specifically (1) when a new sharp blade is used in a razor having a large effective shaving angle, (2) when thin lathers or plain hot water is used, (3) when the skin is excessively stretched, (4) when the shaving is against the "grain," (5) when the face is shaved over more than once, and (6) when the pressure between the razor and the face is increased

Traumatism also increased as the preparational period was shortened or inadequate. It decreased when the interval between shaves was extended to two days or

TABLE 4—*Quantity of Skin and Hair Removed in Shaving (Comparison for Average and Close Shaving)*

Test Number	Quantity in Cc		Notes
	Skin	Hair	
39	0 11	0 22	Once over dull blade
40	0 15	0 05	Second time sharp blade
6	0 32	0 28	Once over fair blade
7	0 04	0 04	Second time sharp blade
26	0 14	0 14	Once over fair blade
27	0 11	0 05	Second time same blade
16	0 28	0 32	Once over fair blade
25	0 50	0 26	Once and twice same person

more. The stiffer latherless cream preparations tended to protect the skin from excessive injury

Of these items, blade sharpness and effective shaving angle were the most important in their relation to gross trauma of the skin. A blade that had been dulled by being used for at least one shave rarely cut into the capillaries on any succeeding shave

9 *Individual Variations*—We have shown in table 3 the amounts of skin and hair removed in each daily shave by different members of the shaving clinic. It will be observed that the relation between the greatest and least of the total quantities is from 1 13 to 0 26, or

a ratio of over 4 to 1. The relative dulling effect on standard safety razor blades for the same subjects was approximately of the same order, but in the case of the extreme examples previously referred to the ratio was 8 to 1. No doubt the differences within the general population are even greater

We also saw great differences in the general condition of the skin of individuals. Some skins were deeply wrinkled, others were not, in some skins the pit around the hairshaft^{18f} was quite deep, in others it was shallow or lacking. In some skins the average angle formed between the hair follicle and the skin surface was very much smaller than in others. When this angle was small, greatly increased effort was required to get a close shave and there was an increased tendency for more conspicuous injury, especially when the stroking was against the "grain."

There were, of course, marked differences in facial contour and in subsurface fat (affecting the resistance of the skin to external pressure)

In certain men the hair was found to have the densest spacing on the upper lip and front of the chin and the least dense on the lower part of the cheek. The hair near the anterior cervical triangle was found to grow out at the smallest angle with the skin, that at the front of the chin the largest (sometimes perpendicular). The extreme values of hair spacing that came under our observation are shown in table 5

TABLE 5—*Size and Distribution of Facial Hair*

	Diameters	Distribution	Hairs per Sq Cm
Face	0 091-0 230 mm	Upper cheek	30- 80
Scalp	0 055-0 084 mm (for reference)	Lower cheek	20- 40
		Upper lip	80 110
		Chin center	70-120

Individuals were found to vary considerably from day to day in their reactions to shaving and in their capacity to dull standard razor blades, even when every effort was made to provide equivalent shaving conditions, including blades of equal quality. Shaving dulled standard blades to a greater extent in summer than in winter, indicating a seasonal variation in certain beard properties

In general, the subjects could be classified according to their reactions to shaving with increasingly dull razor blades. In one large class were those to whom the increasing discomfort was the governing factor for discarding a dull blade. In this class were many but not all the men whose shaving dulled blades rapidly. A second class consisted of those to whom increased effort for getting a close shave was the governing factor, discomfort being a minor or inconspicuous item in their judgment. In this class were most of those who dulled standard blades much less than the average figure

The coloring of the individual gave little indication of his beard growth. Two of the blonds were among the four men having the greatest dulling effect and the coarsest hair, whereas two of the brunets were among those having slight blade damaging effect

10 *The Care of the Face After Shaving*—As we have shown in section 8, daily shaving removes in addition to the hair a fair quantity of epidermis, and this action traumatizes the skin of the bearded regions to some extent. Even the person who is not sensitive to the discomforts of these minor traumas benefits from proper after-shaving care. The purposes of such care include (1) the control of bleeding when the skin has been cut, (2) the antiseptic and astringent action

needed, and (3) the replacing of a protective covering lost by the removal of sebum and epidermis

To control bleeding we recommend the use of bismuth subgallate,^{10a} which acts as a styptic without causing any burning or any other sensation. It is preferable particularly because, being a powder, it can be kept and applied aseptically.

As an antiseptic we have used 50 per cent ethyl alcohol, 70 per cent ethyl alcohol, and 50 per cent ethyl alcohol containing 4 per cent salicylic acid. All these solutions have been found satisfactory.

Talcum powder tinted to lessen its white sheen acts well as a protective coating.

It is our belief that the utilization of these materials in after-shaving treatment of the skin adds a good deal of comfort to the daily procedure of shaving.

HOW TO SHAVE MOST SATISFACTORILY

Satisfactory shaving in normal health may be specified as that in which there is an optimum combination of freedom from discomfort, little effort for close shaving and minimum damage to the skin. Our previous discussion shows that blade sharpness and razor design are inextricably interwoven, they cannot be specified in definite terms because of the wide variation in individual tastes and requirements. Generally speaking, men to whom discomfort of shaving is an important item will require a smaller effective shaving angle and sharper blades than will men having insensitive skins. The same is true in the case of men having particularly thin horny layers of epidermis.

In providing satisfactory shaving for himself the individual can go a long way by means of adequate facial preparation. The best procedure found by us is as follows:

Wash the face first with soap and water, using hot water and some toilet soap that has been found not to irritate the skin. Carry on this operation for about one-half minute and then rinse the face thoroughly. The purpose of this washing is to remove the grit from the face, which might damage the blade, and to remove the external layer of sweat and sebum from the skin and hair, as well as other extraneous material. After the soap has been thoroughly rinsed off with hot water, a second layer of soap should be applied. This may be one's favorite shaving soap. It is to be thoroughly rubbed into the surface of the skin with the hand, copious amounts of water being used. These two operations should be made to consume from two and one-half to three minutes.

If latherless cream is preferred for shaving, it should be applied on top of the soap and should be rubbed around enough to mix thoroughly with the lather. If lather-forming soap is to be used, it should be whipped into a lather with a shaving brush. When this lathering is completed, no harm will be done by extending the time the face is in contact with the soap by finding other things to do at this time, such as brushing the teeth or reloading the razor.

Shaving should be begun by wetting the razor with hot water and keeping the face well lathered, both the razor and the face should be kept wet during the entire operation. It is good practice to shave the less difficult portions of the face first, in order that the more difficult portions shall have the benefit of a still longer contact with water. Following shaving the preferred lotion or other post-shaving preparation can be used after the soap has all been rinsed thoroughly from the face.

Mechanical and chemical traumas associated with the operations of shaving produce in certain men an

abnormal feeling, a hypersensitivity of the face. Good shaving practice includes in its purposes the minimizing of this feeling. For the hypersensitive person we propose the adoption of one of the following changes in the preparational operations: (1) the use of cold water for the final lathering procedure, following the hot water preparational period, or (2) the use of menthol incorporated with the shaving soap or cream.

CLINICAL RESULTS OF ANTERIOR PITUITARY THERAPY IN CHILDREN

A WILMOT JACOBSEN, M.D.

AND

ARTHUR J. CRAMER JR., M.D.

BUFFALO

During the past few years medical literature has contained a constantly increasing number of papers dealing with the anterior pituitary gland. Yet, while there has been recorded a tremendous mass of experimental data demonstrating striking effects of administration of

Fig 1 (case 1)—Appearance of patient at beginning of treatment

anterior pituitary substances to animals, there remains a great discrepancy between laboratory knowledge of these substances and their clinical application. Indeed, among conservative clinicians there exists a widespread skepticism as to their value.

Critical clinical reports are few, and it therefore seems worth while to record our own experience with the use of anterior pituitary extracts in children. We have tried them in a variety of conditions such as dwarfism, infantilism, hypogonadism, obesity of the Frohlich type and a few of mental or emotional imbalance. All these children received careful investigations, which included blood studies with chemistry as indicated, basal metabolism determinations, x-ray examination of the osseous system and other special exam-

inations whenever required. Throughout the course of these therapeutic experiments we have attempted to compare periods of treatment with adequate control

Fig 2 (case 1)—Six months later. Note loss of excess fat disappearance of the high waist line and change in facies

Fig 3 (case 1)—Twenty months later. There has been no return to former appearance, although no treatment has been given for fourteen months

periods during which no treatment was given. In order to facilitate the drawing of conclusions, we have tried as far as possible to avoid polyglandular therapy. Once we had convinced ourselves, however, that clinical results could be obtained by the use of commercial pituitary extracts, it seemed unwise to continue to withhold thyroid extract in a case apparently deficient in both thyroid and pituitary secretion. Therefore, after demonstrating the lesser effects of either product when used alone, we have often combined them.

In this paper we present briefly a selected group of children who have received anterior pituitary therapy.

CASE 1—History—V P, a boy, aged 11 years, was first seen at this age, at which time his weight was 109 pounds (49 Kg) and his height 56 inches (142 cm). A diagnosis of hypopituitarism was made because of the type of fat distribution. No treatment was given. He was next seen two years later, at the age of 13 years. At this time his height was 62 inches (157 cm) and his weight 176 pounds (80 Kg), a

Fig 4 (case 2)—A at beginning of treatment. Note the undescended right testis. B six months later. Note loss of fat maturing of facies presence of right testis in scrotum. C eighteen months after beginning of treatment.

gain of 6 inches (15 cm) in height and 67 pounds (30 Kg) in weight during the two years. Physical examination revealed generalized obesity with fat localized particularly about the breasts, scapulae, pubis and hips, giving the characteristic high waist line. The face was rather pudgy, resembling the facies commonly seen in hypothyroidism. The external genitalia were normally developed, with abundant pubic hair, which had a female type of distribution. His actions and mannerisms were rather feminine.

Treatment—One cc of anterior pituitary extract¹ was given twice a week for six months. There was no thyroid given and no curtailing of food intake.

Result—During the six months he gained 1½ inches (3.8 cm) in height and lost 26 pounds (12 Kg) in weight. His facial appearance completely changed, fat pads disappeared and his actions and manner became more masculine.

Seen again fourteen months after discontinuing injections, he had not lost ground in any way and his weight remained at 145 pounds (66 Kg). A recent visit three years after treatment was begun shows the boy to be entirely normal.

¹ The anterior pituitary extract used in this study was autotrin (Parke Davis & Co.)

CASE 2—History—F H, a boy, aged 12 years, was of normal size until he was 8, since which time he had gained weight rapidly. At the first visit, Feb 2, 1934, his weight was 161 pounds (73 Kg) and his height 62½ inches (159 cm). He was obese, with the fat localized particularly about the trunk. The genitalia were small, the left testis was in the scrotum and the right in the canal at the external ring. X-ray films showed a slight retardation of the epiphyseal centers.

Treatment—Anterior pituitary extract 1 cc was given twice a week, and thyroid from 1 to 4 grains (0.06 to 0.26 Gm) daily as tolerated.

Result—Therapy was continued for ten months, during which period he lost 27 pounds (12 Kg) and gained 2 inches (5 cm) in height. Localized fat pads disappeared. The right testis descended into the scrotum and the genitalia developed normally. One year after discontinuance of treatment the boy was normal in appearance.

CASE 3—History—N M, a boy, aged 13 years, admitted to the hospital in the orthopedic service, complained of an old

156½ pounds (71 Kg) and his height was 60¾ inches (154 cm). Excessive fat localized chiefly about the trunk and hips and hypogonadism were found on physical examination. X-ray

Fig 6 (case 3)—Fifteen months later, showing loss of fat, normal genital development, maturing of facies.

Fig 5 (case 3)—At beginning of treatment. Note excess fat about trunk, normal extremities (a traumatic injury to the right hip accounts for the stance) and poorly developed genitalia.

hip injury. He was obese with fat deposits chiefly about the trunk and face, the extremities being rather slender.

X-ray films showed slight retardation of development of the bone centers, and the basal metabolic rate varied between -7 and -17 .

Treatment—For eleven months thyroid was given in doses varying from 2 to 6 grains (0.13 to 0.4 Gm) a day. Very little change was noted in his condition. His weight at the start was 138 pounds (63 Kg) and at the end of eleven months 137 pounds (62 Kg), he had gained 3 inches (7.6 cm) in height.

During the next four months thyroid was continued, and in addition 1 cc. of anterior pituitary extract was given three times a week. Most of the improvement as noted in figure 6 occurred during this four months period.

Result—All treatment was then discontinued and six months later his weight had not increased and there was no reaccumulation of the fat pads, which had disappeared during the course of treatment.

CASE 4—History—H Z, a boy, aged 12½ years, was brought to the clinic May 1, 1935, because of a rapid weight increase since he was 9 years of age. On admission he weighed

Fig 7 (case 4)—At beginning of treatment.

films of the epiphyseal centers showed normal bone development. Basal metabolism was -3 and blood chemistry was normal.

Treatment—During the first four months anterior pituitary extract 2 cc was given subcutaneously twice a week, then for six months desiccated thyroid to tolerance (from 15 to 18 grains, or 1 to 11 Gm daily) followed by four months of combination anterior pituitary and thyroid therapy.

Result—On anterior pituitary therapy alone the patient lost 6 pounds (2.7 Kg). The total weight loss for the fourteen months of treatment was only 10½ pounds (4.7 Kg), the

Fig 8 (case 4)—One year later showing redistribution of body fat and increase in size of genitalia

height increase 26 inches (66 cm). These figures are not nearly as indicative of the results obtained as are the views shown in figures 7 and 8, which were taken at the beginning and the end of the fourteen months period. Change in facial appearance with redistribution of fat and some increase in the size of the genitalia may be noted.

At present the boy is continuing under thyroid and anterior pituitary therapy.

CASE 5—History—E M, a girl, aged 13 years, seen in the outpatient department Sept 8, 1931, complained of obesity. At

Fig 9 (case 5)—A at beginning of treatment B eight months later and C seventeen months after beginning of treatment. Change of facial appearance is similar to that which occurred in case 1. Such a change did not occur in this girl while she was being treated with thyroid alone.

that time her weight was 174 pounds (79 Kg), about 64 pounds (29 Kg) overweight. The basal metabolic rate was -22 and x-ray films of the skull and epiphysis were negative. She was treated by diet restriction, thyroid and ovarian extract by injection for six months, with no apparent results. In fact she gained 5 pounds (2.3 Kg) during this period. Nov 7, 1933, she was referred to the endocrine clinic. At this time her weight was 197 pounds (89 Kg).

Treatment—A combination was given of thyroid as tolerated to 6 grains (0.4 Gm) daily and anterior pituitary extract 1 cc twice a week for twelve months. The last four months also included posterior lobe extract (solution of posterior pituitary) in a tolerance dose twice a week.

Results—After twelve months of treatment her weight was 160 pounds (72.6 Kg), a loss of 37 pounds (17 Kg). The height increased only slightly, since the epiphyseal centers had begun to close. Although the obesity has not been entirely corrected, the general appearance and especially the facial features are completely changed. Schoolmates did not recognize the girl when she returned to school after a summer of treatment.

CASE 6—History—D N, a girl, aged 8 years, had been obese since she was 2 years of age and had gained weight with especial rapidity since the age of 5 years. Previous treatment with whole pituitary substance by mouth and a strict dietary regimen had produced poor results. At the first visit, March

Fig 10 (case 6)—At beginning of treatment

19, 1935, the child weighed 128 pounds (58 Kg) and her height was 54.7 inches (139 cm). She was of short stature and obese, with fat localized over the abdomen, pubis, breasts and scapulae. X-ray films showed normal epiphyseal development. The basal metabolic rate was -10.

Treatment—Anterior pituitary extract 1 cc subcutaneously four times a week was administered by the mother at home, a total of fifty-two injections. Thyroid 1 to 4 grains (0.06 to 0.26 Gm) daily was given as tolerated.

Result—Treatment was continued sixteen months, during which period there occurred a loss of 17 pounds (7.7 Kg) and growth of 3.7 inches (9 cm). The child's appearance is now practically normal and there has been a great improvement in her mental reactions.

CASE 7—History—T S, the brother of J S (case 8), aged 15 years, was normal except for moderate obesity (weight 130 pounds, or 68 Kg) and a feminine distribution of the pubic hair. During the next fifteen months he gained 33 pounds (15 Kg) in spite of efforts to reduce his caloric intake.

Treatment—Thyroid was given in increasing dosage until 6 grains (0.4 Gm) a day was reached, at which level it was maintained. Anterior pituitary extract 1 cc was given twice a week.

Result—Over a period of seven months his weight fell from 185 pounds to 150½ pounds (84 to 69 Kg) and he gained 1 inch (2.5 cm) in height.

Treatment was then stopped for four months, at the end of which time his weight had risen to 169 pounds (77 Kg)

He was then started on thyroid alone, the dosage being quickly increased to 6 grains a day. This was continued for two months, during which time his weight had increased to 174½ pounds (79 Kg). Thus thyroid alone did not produce the weight loss which occurred one year previously under combined thyroid and anterior pituitary therapy.

CASE 8—History—J S, the brother of T S (case 7), aged 14 years, Oct 9, 1933, was moderately obese (weight 133 pounds, or 60.3 Kg), the genitalia were somewhat smaller than usual and pubic hair was scarcely visible.

Treatment—Thyroid was given in increasing dosage until a dose of 6 grains a day was reached, at which level it was maintained. Anterior pituitary extract 1 cc was given twice a week.

Fig 11 (case 6)—Fifteen months later. Note loss of babyish appearance.

Result—During five months of this regimen the boy lost 28 pounds (13 Kg) and gained 1 inch in height.

The boy then failed to take any medication over a period of five months, during which time he gained from 104¼ to 134¼ pounds (47.5 to 61 Kg), approximately the same as his weight before treatment had been started.

He was then given thyroid alone and the dose was increased to 6 grains (0.4 Gm) a day. The full dose was reached within a period of three weeks, whereas during the first course of treatment thirty-six days was required to reach this dosage.

After five weeks the patient became discouraged and did not return for further treatment, but during this period he had lost only 4 pounds (1.8 Kg), whereas one year previously in the same period of time a smaller total thyroid dosage, but with the addition of anterior pituitary extract had produced a loss double this amount.

This case appears to be a less striking example of the same reaction that occurred in this boy's brother (case 8), who actually gained weight when thyroid alone was used.

CASE 9—History—B S, a girl, aged 13 years, had grown very slowly since the age of 7 years and was not maturing as her parents observed other girls of her age were. Her height was 50 inches (127 cm), about 8 inches (20 cm) below the minimum normal figure for this age and 12 inches (30 cm)

below the maximum normal. She gave the appearance of a normal 9 year old girl.

She was observed for seven months without treatment, at the end of which time her height had not changed.

Fig 12 (case 7)—Weight curve.

Treatment—Anterior pituitary substance by mouth 6 grains (0.4 Gm) a day was given for seven months, during which time she grew 2 inches (5 cm) in height. Then for nine months this dose was continued and thyroid up to 2 grains (0.13 Gm) a day was given in addition.

Fig 13 (case 8)—At beginning of treatment.

She was now 15½ years old. During the next four months she received twenty-five injections of anterior pituitary extract. Because no menstruation had yet occurred, extract of pregnancy urine was added. Two weeks later the first menstruation occurred and has continued in normal rhythm ever since.

Result—Her height gain was approximately 5 inches (127 cm) in two years of treatment, which is considerably above average for this age and a good result considering her very slow gain in previous years. There was satisfactory development of secondary sex characteristics.

CASE 10—History—I D., when first seen at the age of 6 years, weighed 23 pounds (10 Kg) and her height was 36 inches (99 cm). She was normally proportioned but markedly

Fig 14 (case 8) —Six months later

undersized for her age. There was no history of severe illness, she was active and alert, and there was nothing to suggest hypothyroidism. X-ray films revealed a normal osseous development. She was observed for two and one-half years, at the end of which time, at the age of 8½ years, she weighed 32 pounds (14.5 Kg), a gain of 4½ pounds (2 Kg) a year, and her height was 40 inches (102 cm), a gain of 16 inches (27 cm) a year. She was then treated as follows:

First six months, anterior pituitary extract plus thyroid. Gain in height 2½ inches (63 cm).

Second six months, no treatment. Gain in height three-fourths inch (29 cm).

Third six months, anterior pituitary extract alone. Gain in height 1¼ inches (32 cm).

This is a gain in height at the rate of 3½ inches (9 cm) a year. During this eighteen months period her weight increased to 45 pounds (20 Kg), a gain of 13 pounds (6 Kg).

COMMENT

From considerable material these cases have been selected as typical of the results that may be obtained when response to anterior pituitary therapy is favorable. We do not wish to imply that such is always the case, for in many patients no improvement is observed or there is only slight or moderate improvement. On the other hand, in spite of the theoretical potentialities for harm in the administration of active endocrine products we have never seen any case in which the slightest evidence of untoward effect could be observed.

In the interest of brevity we have refrained from including full descriptions of the physical characteristics of these children, feeling that the illustrations show clearly the type of case with which we were dealing and also the results of therapy. Unfortunately no picture or chart can depict the mental and emotional transformation that occurs in some of these children coincident with the physical change. A shy, timid inhibited boy without friends becomes pugnacious, self-assured and a class leader. A girl whose only interest has been books begins to take an active part in outdoor sports. Teachers often report an improvement in scholarship. In the case of one boy who had been receiving anterior pituitary extract for three months with no physical effect that could be observed the mother was informed that the course of treatment was now completed and that no more would be required. She departed entirely satisfied only to return a few weeks later demanding that the injections be resumed because the child's actions at home and his reports from school had been so much better while he was under treatment. In spite of numerous apparently authentic reports of this sort we feel that it is difficult to evaluate the action of the administration of anterior pituitary on the psyche. Parents frequently report a variety of desired behavior changes beginning almost immediately after the start of injections, but it is our opinion that most of these observations are due to reaction of the eager parents themselves rather than of the patient. Later on, however, when the child's physical proportions begin to approach normal, there can be no doubt that there occurs a very real change in mental outlook and secondarily in behavior.

We have repeatedly observed that combined anterior pituitary and thyroid therapy is apt to produce more striking improvement than either extract used alone. For example in cases 7 and 8 the two brothers lost excess weight rapidly under the influence of combined therapy. On discontinuance of treatment they returned to their original status. When an attempt was made one year later to repeat the process but with thyroid alone, since the patients refused more injections, both boys became discouraged after two months and stopped treatment because they failed to observe any improvement. Case 5 is another example of failure with dietary restriction plus thyroid but of good results with anterior pituitary extract plus thyroid. In reviewing our material we find that very often our zeal to secure maximum clinical results has led us to add thyroid early in the course of treatment, thus obscuring

Fig 15 (case 9) —At beginning of treatment showing infantile appearance as compared with a normal girl of the same age

the effects of the administration of anterior pituitary extract and rendering the case inconclusive so far as its reporting is concerned. Hence we have relatively few patients to whom thyroid has not been given at some time while under observation. It is certain, however, that formerly when we treated similar cases with thyroid alone we were unable to secure results comparable to those obtained fairly regularly since anterior pituitary extract has been available.

An example of the occasionally completely satisfactory results of anterior pituitary therapy alone is seen in case 1. No more striking proof than this of the potency of an extract could be desired, since this boy up until the start of treatment had been gaining weight at an extraordinary rate over a period of at least two years. Loss of weight began with the first injection

and continued during the six months of treatment. Thyroid was not given and food intake was not restricted. There was normal sexual development in this case and so it cannot be classified as Frohlich's syndrome, but that the obesity was the result of primary pituitary dysfunction is proved by the therapeutic test. As a result of the administration of anterior pituitary there must have taken place some sort of readjustment of endocrine balance, similar perhaps to that which often, but by no means always, occurs at puberty. In any event no further treatment has been required and at the end of three

years the boy remains quite normal. At present we are unable to predict which cases will require prolonged treatment and which will react as did this boy.

by the time the hoped for change does take place many a sensitive child has come to feel, because of the obvious peculiarities of his physical make-up, that he is a freak, a being set apart from others and untold and often irreparable psychic damage has been done. To us it would seem advisable, therefore, to treat these children whenever they are discovered, preferring the theoretical danger of some sort of endocrine overstimulation to the very real danger of a psychic injury which may leave a permanent impress on the personality.

Whenever hypogonadism is a prominent feature we have found it advisable to give in addition to other therapy the anterior pituitary-like substance derived from pregnancy urine. This usually produces a fairly prompt effect, as indicated by descent of testes and an increase in the size of genitalia in males, and

Fig 16 (case 9)—Twenty months later standing beside the same girl in figure 15. Note relative heights.

Fig 17 (case 10)—At the age of 8½ years beside a normal body of the same age.

Fig 18 (case 10)—A at beginning of treatment B eighteen months later.

increased breast development and onset of menstruation in females. An example of the latter effect is seen in patient 9, a girl who at the age of 15½ years had

not menstruated Fourteen days after the first dose of pregnancy urine extract, menstruation occurred

SUMMARY

Ten cases are reported of children who have received therapy with anterior pituitary extract These were selected as illustrative of the kind of results that may be obtained in cases of dwarfism, infantilism, hypogonadism and certain types of obesity when the response to endocrine treatment is favorable

Experience has shown that desiccated thyroid administered in conjunction with anterior pituitary extract usually produces more rapid improvement than anterior pituitary extract given alone Patients who have failed to respond when thyroid alone was given have improved rapidly on combined therapy

SYNDROME OF HYPOCHROMIC ANEMIA, ACHLORHYDRIA AND ATROPHIC GASTRITIS

GASTROSCOPIC STUDIES, WITH CASE REPORTS

LESTER M MORRISON, M.D.

WILLIAM A SWALM, M.D.

AND

CHEVALIER L JACKSON, M.D.

PHILADELPHIA

During a review of 400 gastroscopies performed as a routine on patients with gastro-intestinal symptoms, it was unexpectedly observed that a group of patients who had a hypochromic anemia and achlorhydria had a definite atrophic gastritis gastroscopically

It is our purpose in this report to present support of our belief that idiopathic hypochromic anemia is the partial expression of a syndrome and not a disease entity, and that it is as yet an unknown metabolic disturbance in which atrophic gastritis plays a dominating rôle This syndrome may be an etiologic factor in the genesis of pernicious anemia, subacute combined degeneration of the cord, and carcinoma of the stomach and esophagus As Osler¹ originally showed in chlorosis, this syndrome is readily amenable to iron therapy, which will effect cure or marked improvement

Owing to the then unrealized occurrence of this syndrome, detailed studies of the erythrocytes, such as their diameter or hematocrit values, were not accomplished This will be included in the follow-up studies However, the low color index, decreased hemoglobin value and comparatively slight reduction in erythrocytes render the blood changes in these cases characteristic of hypochromic anemia

Practically all these patients had received some treatment in medical clinics before they were referred to the gastro-intestinal clinic, accounting for an absence of a very severe anemia except in cases 2 and 9 in the accompanying table

Case 2, a typical Plummer-Vinson syndrome, was observed to present an atrophic gastritis, which is perhaps a feature of this syndrome

The classification of atrophic gastritis in three stages, as employed by Moutier² and based on pathologic changes in gastric structure, is adhered to owing to its

greater accuracy, especially from the standpoints of genetic and etiologic development As Chevalier Jackson³ has pointed out, the present classification of chronic gastritis into four main groups is inadequate, and probably as many as thirty divisions and subdivisions are necessary in a more thorough evaluation of the significance of the visualized gastric changes from a developmental point of view

As already described,⁴ there are two main forms of chronic atrophic gastritis—the diffuse and the segmented—which occur in three stages of involvement, as demonstrated pathologically by Moutier,² namely, (1) thinning out of the mucosa (early involvement), (2) effacement of the gastric rugae (moderately advanced involvement) and (3) arborization of the underlying and submucosal vessels (well advanced involvement)

The changes in the mucosal aspects of the stomach, when studied by the gastroscope, range from a smoothed, velvety, pale whitish rose color of the first stage to the loss of rugal markings, characteristic of the second stage, through various shades of marked pallor to a dead porcelain hue of the third stage The segmented forms are usually seen in the fundus and may occur as plaques

There has been one previous case gastroscopically described by Chevallier⁵ and Moutier⁶ of chlorosis and of idiopathic hypochromic anemia with atrophic gastritis

There has been a decided tendency in the past few years to consider "idiopathic hypochromic anemia" as a distinct disease entity, although when Faber⁷ originally described it in 1909 his contention was, as later reiterated,⁸ that the achylia is really a "complication" of the anemia This appears to be borne out particularly by the demonstrations of Alvarez and Vanzant⁹ that when the hemoglobin falls to a point below 12 Gm or 72 per cent there is a corresponding fall in gastric acidity with a rapid rise in the incidence of gastric achlorhydria Apperly¹⁰ has also shown that when the hemoglobin of the blood approximates an average of two thirds of the normal value, achlorhydria frequently occurs, that is, anemia can bring about achlorhydria This is in contrast with the opinion of Bloomfield and Keefer¹¹ and of Hurst,¹² who believe that anemia does not cause impairment in the gastric secretion However, in support of Alvarez and Vanzant and of Apperly it has been shown¹³ that, on treatment of the anemia in these cases, free hydrochloric acid can return concomitant with improvement in gastric function

Recently there has been considerable investigation of idiopathic hypochromic anemia,¹⁴ particularly by Witts, who has gone so far as to differentiate sharply chlorosis and idiopathic hypochromic anemia by the presence of free acidity in the former and none in the latter. In the study of "early" chlorosis^{14a} and "late"¹⁵ chlorosis past the age of 30, Witts found the disease identical with idiopathic hypochromic anemia, except that free hydrochloric acid was present in the gastric secretions of the chlorotic patients. This of course was based on the classic concept that chlorosis occurred only in young girls, whereas idiopathic hypochromic anemia was found usually among middle-aged women, particularly between 35 and 50.

Wintrobe and Beebe,¹⁷ who found normal gastric secretion in two out of twenty-four cases—ten of the twenty-four presented hypochlorhydria, and the remaining twelve showed a histamine achlorhydria.

The absence of free gastric acidity in conjunction with some unknown gastric factor may account for the hypochromic anemia that occurs in gastrectomized patients¹⁸ and gastrectomized dogs.¹⁹ This factor may be some indeterminate hormone that is linked with hemoglobin regeneration in something of the manner in which achylia gastrica is related to bone marrow function in pernicious anemia.

Weiner and Kaznelson²⁰ have examined the bone marrow in a number of cases of idiopathic hypochromic

Observations in Eleven Cases

Case, Sex and Age	Clinical Picture	Examination of Blood	Gastric Analysis	Gastroscope Appearance
1 B D (♂) 52	(a) Continuous gassy distress and belching daily for 12 years (b) nervousness	Hb 54%, 0.0 Gm erythrocytes 4,300,000 anisocytosis polikilocytosis achromia color index 0.60	Histamine achlorhydria occult blood +4 mucus +1 increase	Numerous areas of marked pallor showing branching of submucosal vessels through the thinned out mucosa which is friable and shows fresh oozing
2 E H (♀) 40	(a) Sensation of lump in throat (b) dysphagia (c) neurasthenia (d) burning sensation in tongue (glossitis)	Hb 36%, 6.0 Gm erythrocytes 4,700,000 anisocytosis polikilocytosis achromia color index 0.40	Histamine achlorhydria occult blood negative mucus +1 increase	Mucosa of fundus completely gray and showing plaques of submucosal arborization of veins
3 H B (♂) 54	(a) Anorexia (b) angus dyspepsia (c) chronic dermatitis herpetiformis	Hb 60%, 10.0 Gm erythrocytes 3,500,000 anisocytosis polikilocytosis achromia color index 0.78	Histamine achlorhydria occult blood negative mucus ± increase	Segmented patches of white mucosa thinned out
4 M O (♀) 57	(a) Dysphagia and food and liquid regurgitations (b) benign esophageal stenosis (c) marked asthenia	Hb 59%, 9.8 Gm erythrocytes 4,300,000 anisocytosis polikilocytosis achromia color index 0.68	Histamine achlorhydria occult blood faint trace mucus +2 increase	Large area of marked pallor involving the fundus with arborization of submucosal vessels and effacement of gastric rugae
5 B R (♀) 52	(a) Gassy abdominal discomfort post prandial (b) vertigo (c) dyspnea (d) burning sensation in tongue (glossitis)	Hb 55%, 9.7 Gm erythrocytes 4,340,000 anisocytosis polikilocytosis achromia color index 0.67	Histamine achlorhydria occult blood faint mucus ± increase	Marked dead white pallor involving entire gastric mucosa with typical effacement of rugae
6 G D (♀) 46	(a) Vomiting of mucus (b) frequent and generalized abdominal distress (c) constant fatigue and constipation	Hb 60%, 10 Gm erythrocytes 4,400,000 color index 0.72	Histamine achlorhydria occult blood +4 mucus +1 increase	Mucosa pale dry glazed effacement of rugae slight amount of thick mucus noted
7 S G (♂) 55	(a) Chronic epigastric distress 3-4 hours after meals (b) vertigo (c) burning sensation in upper abdomen	Hb 56%, 0.4 Gm erythrocytes 4,210,000 anisocytosis polikilocytosis achromia color index 0.66	Histamine achlorhydria occult blood +4 mucus +3 increase	Mucosa markedly pallid in segmented areas with complete mucosal thinning and arborization of submucosal vessels patches of tenacious mucus seen
8 M T (♀) 48	(a) Circumscribed upper abdominal distress after meals of 10 years duration (b) marked nervousness and weakness	Hb 50%, 9.8 Gm erythrocytes 4,100,000 anisocytosis polikilocytosis achromia color index 0.72	Histamine achlorhydria occult blood +3 mucus +3 increase	Entire gastric mucosa whitened rugae flattened out marked arborization of vessels in cardia portion mucoid patches seen
9 J O (♀)	(a) Pyrosis gassy distress and belching after meals (1½ years) (b) nausea after meals (3 weeks) (c) marked asthenia	Hb 37.5%, 6.3 Gm erythrocytes 3,100,000 anisocytosis polikilocytosis achromia color index 0.61	Histamine achlorhydria occult blood +1 mucus +3 increase	Marked white appearance entire gastric mucosa with striking picture of vascular arborization and complete thinning out of mucosa increased mucus
10 M G (♀)	(a) Chronic dyspepsia (b) pains in upper abdomen (c) constipation	Hb 57%, 9.5 Gm erythrocytes 4,001,000 anisocytosis polikilocytosis achromia color index 0.71	Hypochlorhydria grade 4 occult blood positive mucus ± increase	Fundus moderately pale pylorus hyperactive slight increase in mucus patchy in distribution
11 Dr A N (♀)	(a) Midepigastric distress after meals (1 year) (b) constant epigastric tenderness (1 year) (c) anorexia (d) gas and belching after meals (1½ years)	Hb 62%, 10.3 Gm erythrocytes 4,040,000 anisocytosis polikilocytosis achromia color index 0.77	Hypo acidity grade 4 occult blood +1 mucus increase +3	Mucosa gray throughout and smoothed out pallor marked in patches no mucus noted small erosions seen

1 All the cases presented radiologically normal stomachs during routine gastro intestinal series

2 In no instance was atrophy of the gastric rugal pattern observed roentgenographically

3 Gallbladder disease was ruled out roentgenographically or by nonsurgical biliary drainage in each case

Patek and Heath¹⁰ described four cases of classic chlorosis between the ages of 15 and 16. One patient was found to have a normal gastric secretion, two had a considerably reduced free gastric acidity and one had a histamine achlorhydria.

That free hydrochloric acid is a frequent occurrence in idiopathic hypochromic anemia has been clearly demonstrated by various authors and particularly by

anemia which showed uniformly red hyperplastic marrow crowded with normoblasts but without megakaryoblasts. Differential counts of bone marrow films showed from 30 to 47 per cent normoblasts to be present, in contrast with the normal value of 20 per cent. Following treatment, one case studied presented a return to the normal percentage of normoblasts. In four cases that came to autopsy red hyperplastic bone marrow was found in one of the long bones. question of a liaison between bone marrow and the stomach is one that would certainly merit further investigation

Likewise Castle and Minot²¹ and Bloomfield²² present considerable evidence to show that chlorosis and idiopathic hypochromic anemia cannot be differentiated into independent entities but are one and the same

The role of dietary inadequacy and malnutrition has been demonstrated by extensive studies by Davidson²³ among the poor of Aberdeen, who were found to have insufficient iron in their diet and a comparatively large part of whom had this hypochromic type of anemia, prompt clinical improvement was noted following adequate iron administration

Alvarez²⁴ has introduced the question of an avitaminosis as an etiologic factor in the production of hypochromic anemia, showing that with diets deficient in vitamin B, the hemoglobin drops about 11 per cent within six weeks and the erythrocytes decrease from 6 to 7 per cent. Similarly, it is known that the dietary restrictions imposed in the management of various gastro-intestinal diseases or food fads may be influential in the production of hypochromic anemia. However, it should be admitted that demonstration of the defective diet as the causative factor in the production of chlorosis really originated in medical and lay writers of earlier centuries, showing that the consideration of improper diet has long antedated our modern data on nutritional deficiency

Levertton and Roberts,²⁵ in a careful investigation, recently showed definitely that menstruation does not have the slightest effect on either hemoglobin or erythrocyte value. Although this study was made in the normal woman, it may tend to discount the belief, commonly expressed, and voiced also by Bloomfield and Polland,²² that the monthly loss of blood through menstruation may be a factor in the production of idiopathic hypochromic anemia. This is of particular significance, since it appears to support the concept that idiopathic hypochromic anemia and chlorosis are one and the same, since "chlorotics" were believed to have scanty menstruation

In contrast with certain observers, we feel as do Castle and Minot²⁶ that the absence or reduction of free acidity in the stomach of patients with lesions of the alimentary tract is of significance as playing a rôle in their pathogenesis

Faber²⁷ has shown most convincingly that in the majority of cases anacidity is principally the result of a disorder of the gastric mucosa or some type of gastritis. By proper fixation of the stomach he demonstrates the signs of chronic inflammation, namely, a diffuse gastritis tending to atrophy

Puchert²⁸ has likewise found that gastritis is more prevalent in cases of anacidity

Henning and Jurgens²⁹ studied the gastroscopic appearances of twenty-nine true achylas following his tamme and noted atrophy of the mucosa in four cases, and severe chronic gastritis in thirteen cases. Blood studies, however, were not reported

This is of great interest, since the occurrence of anacidity in the general population varies directly in proportion to the age limit. Vanzant and Alvarez and their associates³⁰ in an investigation of 3,381 patients at the Mayo Clinic who were free of known gastro-intestinal disease found anacidity in 14.5 per cent; this figure rose consistently up to the age of 70. Bloomfield³¹ and Polland³² in collected material of 5,207 cases examined for acid values found the incidence of achlorhydria to range from 5.3 per cent in the third decade of life to 35.4 per cent in the seventh decade

It thus becomes apparent in noting the wide occurrence of anacidity that the contention of Faber and Hurst is of the greatest significance. They believe that the main cause of anacidity is gastritis, which in turn is the precursor of carcinoma of the stomach, pernicious anemia, combined sclerosis and less clearly defined disabilities, featured by diarrhea and sore mouth

Mathieu³³ in 1889 was among the first to set forth clearly the belief, based on clinical and pathologic studies, that a preexisting gastritis is responsible for the subsequent development of carcinoma of the stomach

Konjetzny,³⁴ in particular, has done considerable pathologic work in support of this theory and has been able to demonstrate very positive evidence in the histologic transitions from gastritis to actual cancer

It is agreed by many investigators that chronic gastritis is frequently symptom free. This is especially true of those who have a constitutional or hereditary diathesis to the development of gastric disease, or those of faulty eating habits such as hasty eaters, alcoholic addicts, or those who bolt hot food or drinks, and those with bad oral hygiene or constant postnasal discharge into the stomach. It must be admitted, however, that there is not an inconsiderable number of the aforementioned indiscreet eaters or drinkers who are found to have perfectly normal stomachs from the standpoint of pathology. This would tend to emphasize the constitutional or hereditary factors

Of especial interest is Ahlbom's³⁵ report from the Cancer Institute of Stockholm that 100 out of 250 cases of squamous cell carcinoma of the mouth, pharynx and esophagus showed evidence of a previous simple achlorhydric anemia or so-called Plummer-Vinson syndrome, previously described by Patterson³⁶ and Kelly³⁷. Ahlbom believes that squamous cell carcinoma has its foundation in the atrophic changes in the mucous membrane

37 Kelly A B Brit J Laryng Rhin & Otol 31 289 (Aug) 1919

Suzman³⁸ has likewise reported epithelial changes of a precancerous type in the mouth and pharyngeal mucous membrane in a case of so-called Plummer-Vinson's syndrome at necropsy. This is of particular note in case 2, presenting Plummer-Vinson's syndrome, in which esophgogscopy revealed an atrophic blanched mucosa concomitant with a marked atrophic gastritis of great pallor. It appears feasible that the esophagus shares in the gastric changes so far as mucosal atrophy is concerned, subject to the same factors in the predispositions to cancer.

Likewise, the relationship between idiopathic hypochromic anemia and pernicious anemia is now conceded by many investigators. Not infrequently idiopathic hypochromic anemia develops into typical pernicious anemia as demonstrated by Wintrobe and Beebe³⁷ and by Heath,³⁹ whereas the association in families of achlorhydria and idiopathic hypochromic anemia was proved by Meulengracht⁴⁰ and by Witts¹⁴ and corroborated since by various authors.

When one realizes the prevalence of gastritis, the most frequent disease of the stomach, occurring in 35 per cent in routine clinic patients with gastro-intestinal complaints in our series,⁴ the significance of the question becomes at once apparent—in view of the devastation of gastric carcinoma.

It is noteworthy that in our group of cases the featured complaints were vague abdominal discomfort with "gas" formation and nervousness and mental depression. The neurogenic factor is of interest in view of Douthwaite's⁴¹ reports supporting Hurst's contention⁴² that neuropoietin is one of the unknown gastric factors that is absent in pernicious anemia and accounts for the changes in the spinal cord. Likewise Douthwaite has shown the close relationship between gastric achlorhydria with gastritis states in patients with polyneuritis, typical muscle wasting, reaction of nerve degeneration and gastric disturbances.

In our group of cases the hypochlorhydrias were presented also, because of our belief that the acid secretion is a link in the metabolic chain between stomach and bone marrow function. It is also possible, as Chevallier and Moutier⁴³ have shown, that further expressions in this complex exist in the skin and tongue, as demonstrated by cases 2, 3 and 5. Complete achlorhydria is one of the end stages of abnormality of secretion in this syndrome reported, whereas considerable hypochlorhydria is found in patients with moderately advanced stages of the syndrome complex, as in cases 10 and 11.

CONCLUSIONS

This study of a group of patients with hypochromic anemia, achlorhydria and hypochlorhydria with atrophic gastritis and its possibility in the genesis of carcinoma of the stomach and esophagus, pernicious anemia and combined sclerosis of the cord is in the nature of a preliminary report, since these cases as well as others will be studied during ensuing years with particular reference to the development of these diseases.

ARTIFICIAL FEVER TREATMENT OF CHOREA

A TWO YEAR STUDY

CLARKE H. BARNACLE, M.D.
JACK R. EWALT, M.D.
AND
FRANKLIN G. EBAUGH, M.D.
DENVER

During the past two years we have treated forty-five cases of Sydenham's chorea with the Kettering hypertherm¹. This study was initiated during the winter of 1935 and is still in progress at the Fever Therapy Department of the University of Colorado. Previously we reported excellent results in thirteen cases, and we have included this group in our present series.

The history of pyretotherapy in chorea dates to von Kern's³ intramuscular injections of milk in 1923. Mas de Ayala⁴ in 1930 was successful in the treatment of chorea by the artificial induction of relapsing fever. The good results of Roeder⁵ and others⁶ with phenylethylhydantoin in the treatment of this disease appeared to be associated with the production of fever. In 1931 Sutton⁷ first called attention to the triple typhoid vaccine method of inducing fever in chorea. Later Sutton and Dodge⁸ reported satisfactory results in 150 attacks of chorea with the typhoid method. These workers felt that the average course of chorea was materially shortened by pyretotherapy. The obvious disadvantage of the methods with foreign protein led to the trial of artificial fever in the treatment of chorea. Neymann,⁹ Desjardins and Popp,¹⁰ Metz,¹¹ Hefke,¹² Wetchler,¹³ and Schnobel and Fetter¹⁴ have all reported excellent results in treating chorea with mechanically induced fever.

From the Fever Therapy Department, University of Colorado Psychopathic Hospital.

Read before the First International Conference on Fever Therapy, New York, March 30, 1937.

1. This apparatus was conceived and perfected at Miami Valley Hospital, Dayton, Ohio, and at the Research Laboratories of the Frigidare Division of the General Motors Corporation, Dayton. Dr. Walter M. Simpson and Mr. Charles F. Kettering of the General Motors Company gave us the privilege of using the apparatus. Three hypertherms are now in constant operation at this clinic.

PROCEDURE

In our clinic we are using three Kettering hypertherms as the means of inducing fever. In the management of the first few cases, fever sessions of two and one-half hours were given at intervals of from three to six days and at temperatures ranging from 103 to 106 F (rectal). Experience convinced us that patients respond more rapidly to daily treatments of two and one-half hours, given at temperatures of from 105 to 105.4 F (rectal). Longer sessions and higher temperatures were tried but were found to be too debilitating, especially in cases complicated by carditis. It

TABLE 1—Results in Treatment of Sydenham's Chorea with the Kettering Hypertherm

Severity	Immediate Results			Recent Follow Up Results			No Follow Up
	No of Patients	Recover ed	Markedly Improved	Recurrence	Recover ed	Markedly Improved	
Severe	14	10	4	2	11	2	1
Moderate	29	25	4	2	23	2	4
Mild	2	2	0	0	2	0	0
Totals	45	37	8	4*	36†	4†	5

* Three patients received two courses of fever

† Four of these patients were previously markedly improved now cured

‡ Three of these patients suffered recurrences

has been our policy to insist on strict rest during these treatments and to prescribe limited activity following the course of fever. Many of the patients were ambulatory and were cared for in the home, while the more severe choreic patients were hospitalized. A cardiologist carefully examined the patients with cardiac involvement and was consulted during the course of their treatment. The progress of the patient was used as a guide to the amount of fever prescribed.

CASES

We have classified the chorea cases as mild, moderate and severe. Mild chorea implies that minimal choreiform movements of an extremity or muscle group are present with trivial functional incapacity. Chorea classified as moderate shows gross choreiform movements of the extremities, trunk or face. Children in this group are unable to perform coordinated acts. They are unable to speak coherently and cannot feed or dress themselves. Hypotonia is a marked symptom. In severe cases there is almost total incapacity. Attempts at voluntary movements result in violent choreiform movements. These patients cannot speak, there is marked difficulty in deglutition, and hypotonia is severe.

In this series there were fourteen severe, twenty-nine moderate and two mild cases. The average duration of symptoms before fever was two months, nine patients had had previous attacks, four had been unsuccessfully treated with triple typhoid vaccine, and the great majority of the other cases had failed to respond to the conservative therapeutic procedures.

RESULTS

In the immediate results of the forty-five patients treated, thirty-seven recovered and eight were markedly improved. We have attempted to follow these patients closely and have succeeded in checking forty of the original number. There have been four recurrences, three of these patients have received a second course of fever. An additional case showed occasional twitching. Thirty-six patients who were followed were cured. Of this number three patients were con-

sidered markedly improved under the immediate results. Four patients were classed markedly improved in the recent follow-up study (table 1).

In table 2 it will be noted that the average number of treatments was 12.6 and the total hours of fever 32.9. The patients were under treatment an average period of 22.3 days. It is interesting to note that a greater number of heatings were needed in the severe type, while the moderate and mild cases required successively less fever.

We found that the presence of carditis, the history of previous attacks and the duration of symptoms prior to fever bore no relationship to the number of heatings required.

The incidence of carditis was 42.2 per cent, that is, nineteen cases. Three of these cases showed evidence of mild decompensation and one presented pericardial effusion. Immediately following pyretotherapy seven patients with carditis had recovered, eight were improved and four were unchanged. The patient with pericardial effusion responded satisfactorily to fever and the effusion disappeared, he is now in school and on full activity twenty months after treatment. Twelve of the nineteen cases of carditis have been carefully checked in recent follow-up examinations. Six patients were cured and are on a full activity program, while six were improved. We have considered all the accepted criteria for carditis in making our diagnosis and arriving at our therapeutic results.

COMMENT

The fact that thirty-six of the forty patients followed in this two year study are found to be cured indicates that pyretotherapy is of lasting benefit. We recognize, however, that this period of time is comparatively short, and further study may prove that the results obtained by this therapeutic method are not sustained.

In the two year period we have had four recurrences among the forty-five patients treated. In one additional patient who suffered from severe chorea occasional muscular twitching has recently developed.

TABLE 2—Treatment of Sydenham's Chorea with Kettering Hypertherm

Severity	Number of Cases	Incidence of Carditis	Average Treatments	Number Hours of Fever	Average Time Under Treatment Days
Severe	14	7	17.9	44.05	39.1
Moderate	29	12	10.3	26.3	19.8
Mild	2	0	9.0	22.5	8.6
Totals	45	19 cases or 42.2%	12.6	39.9	22.3

It will be noted that eight patients, in the immediate results, were markedly improved. In all these choreic patients a maximum amount of fifty hours of fever was given, but occasional choreiform movements continued. It was our opinion that additional heatings would not benefit these particular children. In the recent follow-up study four of these patients were found to have recovered, two had recurrences and two could not be checked.

Through experimentation we agreed that short treatments of two and one-half hours' duration at temperatures of from 105 to 105.4 F (rectal) are most effective if given daily. Longer treatments are necessarily more fatiguing, result in loss of weight, and are dangerous in the face of a complicating carditis. Although fewer fever sessions may be given if the duration of the tem-

perature is longer, the actual hours of fever are approximately the same in the two instances. Daily sessions of short duration do not result in loss of weight nor do they interfere with the child's appetite. Occasionally if the child is markedly emaciated and suffering from severe carditis the interval of treatment is increased to two or three days. The average time under treatment for all patients with chorea was approximately three weeks, the severe cases boosting up the average.

In other studies we¹⁵ have reported the incidence of delirium associated with artificial fever. It is interesting to note that in the 562 treatments administered to forty-five chorea patients there were only twelve deliriums, six of these were mild, five were moderate and one was classic or severe. This incidence is in sharp contrast to the common belief that children are hypersusceptible to delirium. The facts that the heatings are short, that sedatives are but rarely necessary and that the children are very comfortable in the Kettering hyperthermia may explain this low incidence. The nurse technician usually reads stories to the children and carries them along in conversations about their daily activity. Children are rarely bothered with postfebrile nausea and retain 2 liters of salinized water without difficulty.

In a preliminary report we confirmed the conclusions of Sutton and Dodge¹⁶ that advanced rheumatic carditis did not contraindicate fever treatment. In fact, we found that the associated carditis was benefited by pyretotherapy. Fifteen of the nineteen patients showed immediate improvement in cardiac function, and twelve of these continued as improved in a recent examination.

SUMMARY

1 In a two year study, forty-five patients¹⁷ with Sydenham's chorea have been treated by artificial fever with the Kettering hyperthermia.

2 Fever sessions of two and one-half hours' duration at temperatures of from 105 to 105.4 F (rectal) are advocated.

3 The average number of treatments was 126, the average number of hours of fever was 329 and the average time under treatment was 22.3 days.

4 The immediate results have been excellent, with recovery in the majority of cases. There have been four recurrences during this period of time. The majority of cases have been followed and the results indicate that pyretotherapy is of lasting benefit.

5 The incidence of carditis was 42.2 per cent (nineteen cases). Carditis did not interfere with the treatment and the majority of the patients were benefited.

6 Associated delirious episodes were infrequent.

Hospital Life—Great hospitals, with their schools, are something more than blocks of buildings where patients are doctored, and students and nurses are taught. I do believe in the spirit of a place. To me, the genius loci is really there and the Religio Discipuli, the student's obedience to the spirit of Hospital life, is a very important part of his education.—Paget, Stephen. *Confessio Medici*, New York, Macmillan Company, 1931.

HAY FEVER AND ASTHMA DURING AND AFTER JAUNDICE

ASCITES DUE TO CINCHOPHEN POISONING

EDWIN BOROS, MD

NEW YORK

Since the publication of the first report of a case of combined jaundice and ascites with recovery by Jones and Minot¹ in 1923, the attention of the profession has been directed to the occurrence of these uncommonly associated conditions, and there have been noted and recorded from time to time similar observations by Bauer,² Weir,³ Meyer and Learner,⁴ McCabe and Hart,⁵ Cavanagh⁶ and others. Among the etiologic factors mentioned as instrumental in the causation of damage to the liver parenchyma sufficient to produce both jaundice and ascites⁷ there may be mentioned arsphenamine, mercurial products, phosphorus, sodium gold thiosulfate, cinchophen, common duct stone, pressure of glands on the common duct, and infections.

As a rather prominent offender, cinchophen has assumed an important role in the production of pathologic changes in the liver. It was discovered by Doebner and Gieseke⁸ in 1887 and gained considerable popularity in the realm of therapeutics until 1913, when John Phillips⁹ published his observations describing its toxic effects. This was soon followed by extended studies on a dog⁹ in which the administration of this product brought about a severe degeneration of the liver with resulting death. With the accumulation of further reports attesting the toxic behavior of this agent on the liver, warnings were broadcast and means were sought to curtail the harmful effects resulting from its usage. Palmer and Woodall¹⁰ made a study as to the possibilities for insuring a safe means of administration of this drug and concluded that such a thing was not possible.

The nature of the liver damage produced by cinchophen or its derivatives is similar to the poisoning produced by phosphorus, chloroform or trinitrotoluene, and the pathologic picture is one in which there is definite evidence of liver damage—local areas of liver necrosis which may extend to the complete disappearance of the hepatic cells. That there is a peculiar idiosyncrasy to the drug in some persons is unquestioned, for fatalities have been encountered even with the smallest of doses, and many times without the merest suggestion of a prodrome. Furthermore, the length of time intervening between the actual administration of the remedy and the onset of symptoms is variable.¹¹ The first toxic effects may appear weeks after the

ingestion and withdrawal of the medication. In referring to 191 cases of jaundice in the past decade which arose after the ingestion of cinchophen or its derivatives, Palmer and Woodall¹⁰ cited a mortality rate of 46.3 per cent. The degree of hepatic involvement depends to some extent on the intensity of the irritation. The pathologic lesion may simulate an acute or subacute yellow atrophy, depending on the severity of the damage, and the production of considerable connective tissue may bring about a true cirrhosis with an extensive atrophy. The rarity of the occurrence of ascites in association with jaundice was noted by Meyer and Learner. Whereas jaundice is a frequent occurrence in disturbances of the liver, its combined existence with ascites is exceptional. In the majority of instances a portal obstruction which is followed by a serous transudation into the peritoneal cavity is regarded as a fatal and terminal sign.

REPORT OF CASE

The following case is presented as an addition to the sparse literature on this subject, plus some unusual and interesting features.

J. W., a man, aged 36, referred by Dr. Morris Stahl, Sept. 11, 1935, complained that he had been jaundiced for well nigh three weeks. His family history was without interest other than that his father had died of carcinoma at the age of 63. His past history revealed the usual childhood illnesses. For the past eight or nine years he had been suffering with hay fever, which affected him during the month of August. The present complaint could be traced to the ingestion of about 100 cinchophen tablets, taken sporadically at intervals over a period of about ten months for the control of rheumatic pains in the right leg. At no time were there more than three tablets ingested within the period of one week. The first symptom noticed was about three weeks prior to this visit, when the patient's body became yellow. Anorexia set in with an associated weakness and malaise. The excreta were observed to vary in color from clay to a dark brown. There was no itching, headache or other nervous manifestation, but it was remarked that during August just preceding the onset of the jaundice the patient had experienced a complete cessation of his hay fever symptoms. Incidentally it was observed that during the interim during which the cinchophen medication had taken place there had occurred no actual freedom from pain but that with the onset of the jaundice all his rheumatic symptoms suddenly cleared up.

On delving further into the nature of the hay fever aspects of his complaint, the patient stated that since the year 1927 he had been afflicted with this disease in a severe form, with the usual symptoms of sneezing, lacrimation, coughing and the like, whose onset appeared promptly, August 15 of each year, which date he soon learned to dread, and would last till cool weather set in. As an added problem to his already existent misery it was noticed that daily throughout the season asthmatic symptoms—coughing, dyspnea and the like appeared in the early hours of the morning and added to the already intolerable burden that he was laboring under, and so, from April to August 1930, he applied at the outpatient department of the Morrisania Hospital, where weekly injections of the dwarf and giant ragweed pollen were administered with a view to ameliorating his complaints. Twenty such injections were given without the slightest improvement in the course of his condition. As time passed, the same rhinorrhea, sneezing and breathlessness asserted themselves without any abatement. Then a momentous thing happened, as noted the entire train of symptoms from which he had been suffering over so many years ceased promptly as jaundice with its attendant hepatic involvement appeared.

On physical examination, the patient's complexion was noticed as being of a dark brownish yellow hue, although he did not appear to be acutely ill. He was well nourished and weighed 164 pounds (74 Kg.). The pulse rate was 74 and the temperature 98.6 F. The heart and lungs were normal. Blood pressure was 125 systolic, 80 diastolic. The abdominal examination demonstrated the presence of a slightly enlarged liver, extend-

ing two fingerbreadths below the costal margin, with a slight sensitivity obtainable on deep pressure. The spleen could not be felt, and percussion revealed a tympanitic note throughout.

A gastro-intestinal x-ray series failed to demonstrate any abnormal conditions in the alimentary tract. A dye test of the gallbladder was not attempted.

The gastric analysis (Ewald meal) yielded a free acidity of 25 and a total acidity of 52. No mucus, blood or lactic acid was present.

The urine was a mahogany brown with a specific gravity of 1.020, it was acid in reaction and showed a trace of sugar and albumin but no acetone or acetic acid.

The stool specimen submitted was brown, urobilin was present and there was evidence of poor fat digestion.

Biliary drainage demonstrated a free flow of bile, which was dark and semiviscid, at times almost black, particularly obtainable in the C bile. Microscopic examination showed the existence of large quantities of cholesterol crystals, considerable debris and a large number of white blood cells.

Chemical examination of the blood revealed cholesterol 165 mg., cholesterol ester 84 mg., urea nitrogen 16 mg., uric acid 1.6 mg., and nonprotein nitrogen 35 mg.

There being no contraindication to gastroscopy, it occurred that since the patient's condition was satisfactory it might be of some value to explore the stomach. Under local anesthesia, a speedy examination of the entire gastric cavity was effected. The gastric mucosa was intensely yellow. Especial care was exercised for the detection of small mucosal changes or vascular departures from normal, as well as for local signs of irritation or inflammation. The mucosa appeared to be completely normal and no specially defined pigment areas could be detected in an otherwise deep tinting, nor were any intervening portions of the inner lining observable which were free from the yellowish discoloration noted. Hemorrhagic spots could not be detected, and it is of interest to note that the instrumentation had not evoked the slightest oozing or damage to the stomach.

September 18 the patient was referred by me to the Bronx Hospital. An icterus index determination yielded a figure of 250 units. The blood examination at this time presented a hemoglobin of 90 per cent, red blood cells 4,700,000, white blood cells 10,500, polymorphonuclears 78 per cent, band forms 2 per cent, small monocytes 15 per cent and monocytes 5 per cent. The van den Bergh reaction was immediate indirect, 10.3 units per hundred cubic centimeters of serum.

The treatment comprised the administration of a high carbohydrate, low fat and low protein diet, with the added administration of from 500 to 1,500 cc. of a 10 per cent solution of dextrose and insulin, intravenous injections of a 10 per cent solution of calcium gluconate daily and daily biliary drainages. The patient seemed to feel distinctly better after the withdrawal of large quantities of bile by means of the duodenal tube, as much as 1,500 cc. being withdrawn on each occasion, without any noticeable ill effect on the patient. During this period there was no elevation of temperature, and the pulse rate ranged between 72 and 100 beats to a minute, the lowest figure to be reached being 60, and that for one day only. The progress toward improvement as far as the patient's color was concerned was somewhat slow. Almost four weeks after his entrance into the hospital, ascites and edema of the ankles set in. At this time the liver edge could barely be palpated and the icterus index registered 50.7 units. Several days later the patient signified his unwillingness to remain at the hospital any longer, choosing to be cared for at his home. There the necessary treatment was continued through a period of gradually receding symptoms, all of which disappeared entirely at the expiration of another ten weeks. Subsequent examinations conducted at intervals of about six months demonstrated no discernible departures from normal. A galactose and bromsulphalein test undertaken to investigate a possible impairment of liver function turned out to be negative.

In the summer of 1936 the patient was in fine physical condition and the expected seasonal occurrence was awaited, but no reminder of his past reactions either as hay fever or as asthma were noted. In short, it appeared that he was perfectly free from his ailment. He ventured as far as to spend two weeks during the latter part of August in the Catskill Mountains, where the ragweed literally abounded in countless numbers, enjoying his stay in complete happiness and comfort,

where formerly such an experience could not be possible without insufferable consequences

After sufficient time had elapsed to permit a so called seasoning of some of the possible underlying conditions or factors that may have been instrumental in the causation of this unusual phenomenon, it was deemed advisable to subject the patient to a series of allergic tests with a view to determining his present status and response. Accordingly an intracutaneous injection of 1,000 pollen units per cubic centimeter of ragweed pollen was administered in the outer aspect of his arm by Dr Milton Kissen. This was followed by the formation of a wheel with a pseudopod configuration, measuring 15 cm in diameter and a flare of 35 cm, demonstrating the existence of a skin sensitivity at the present time. A small quantity of a short ragweed pollen was then placed on a small stick and the powder was inhaled through the nostrils with the absence of any response. It was now decided to apply a small amount of this same pollen into the right eye, the left eye being used as a control. Within five minutes a very mild degree of congestion of the conjunctiva ensued unaccompanied by lacrimation. There were no signs of itching, fulness or discomfort. In order to establish definitely that no mechanical factor was responsible for the irritation observed, black walnut pollen was instilled into the left eye without the production of any definite changes.

COMMENT

The slowness in the retrogression of symptoms is in accord with previous observations relative to the tenacity with which impairment of the liver persists. However, there is no better testimony as to the remarkable regenerative powers of this organ than the complete restoration of the patient to normal health in the face of such a severe lesion.

An unusual feature of this case is the interesting statement by the patient that with the onset of the jaundice a complete clinical disappearance of his sensitivity to ragweed occurred. While it is conceded that after a protracted siege of hay fever there may occur a natural tendency toward the improvement of symptoms as time goes on, a complete disappearance such as was experienced in the case referred to is exceedingly rare. Is there something normally formed within the liver which has to do with a patient being allergic, and is it possible that with a certain degree or type of liver involvement such as occurred in this patient that causative agent would be destroyed? That food allergy is capable of producing abdominal symptoms which may simulate liver disease has been well known.¹² Manwaring¹³ and others¹⁴ have noted that an allergic reaction in the liver may ensue as a consequence of a disordered sensitivity to food, and he was able to demonstrate that the complete extirpation of this organ in an anaphylactic dog prevented anaphylaxis in the animal. Whether there is an analogy in the behavior of an inhaled pollen such as ragweed to an allergic producing food substance as described is problematic.

In a patient with hay fever who has been subjected to treatment, the positive and negative responses demonstrated in this case have been known to occur, but then only on rare occasions, it being considered exceptional. It is likewise a rare occurrence for a patient to lose his clinical sensitivity in a sudden manner, although, as emphasized previously, in a protracted disease one may expect a gradual fading in the intensity of his symptoms. It would not be amiss to note that clinical sensitivity and skin sensitivity are two different things. The presence of clinical sensitivity presupposes and establishes the existence of a concomitant skin sen-

sitivity. To this rule there are but few exceptions, but where one is confronted by a skin reaction it does not necessarily follow that clinical manifestations must coexist.

I am convinced that, as far as could be determined, the patient after recovery presented no discernible signs or complaints which could be used as a basis to predicate any noticeable transformation in the organ. That there might be some chemical or physical change as a sequel to his liver injury can be surmised but just what constitutes this change is speculative and merits further study. A significant observation not without interest is the disappearance of pain simultaneously with the ushering in of the jaundice. This might be purely coincidental. Since the obliteration of all vestiges of the hepatic involvement, no cause has arisen for complaint relative to his previous rheumatic tendency.

SUMMARY

The extraordinary recuperative powers of the liver subsequent to a severe toxic injury producing the rare combination of jaundice and ascites with recovery is demonstrated with an unusual phenomenon entailing the disappearance of clinical allergy in the same patient with the advent of a serious hepatic degeneration. If the formation of ascites could be attributed to portal obstruction resulting from the proliferation of connective tissue, even signs of a minor degree pointing to this cause could not be demonstrated in the stomach after gastroscopic visualization. Certainly an earlier case of portal cirrhosis could scarcely have been studied.

NONSPECIFICITY OF GONADOTROPIC FACTOR OF PREGNANCY URINE INTRADERMALLY

AS A TEST FOR PREGNANCY

BERNARD SCHNEIDER, MD, DNB

AND

ARMAND E COHEN, MD

Associate Professor of Medicine, University of Louisville
School of Medicine
LOUISVILLE, KY

A recent report¹ on the use of antuitrin-S² intradermally as a test for pregnancy and certain gynecologic conditions aroused our curiosity, since the results reported were at variance with the observations of one of us (A. E. C.) in allergic individuals.

The great number of names given to various glandular products, similar in many respects, has caused much confusion. Some authors have been careless in giving details regarding the product employed and have failed to give information on its source. We have attempted to clarify this situation as far as this intradermal test is concerned.

Mazer and Goldstein³ mention a skin test for pregnancy as follows: "Porges and Pollaczek,⁴ working on the hypothesis that pregnant women whose blood is surcharged with the anterior pituitary sex hormone are desensitized to its effects, and that nonpregnant women

Originally they claimed great accuracy (98 per cent) but later they reported an 18 per cent incidence of error in their tested cases.⁵ In a subsequent report by Deutsch⁶ it is clear that the originators of this test used a gonadotropic extract of pregnancy urine ("prolan") and that they injected it intracutaneously. Deutsch found the test to be quite unreliable. That Porges and Pollaczek employed the gonadotropic extract intracutaneously is further borne out by the Vienna letter in THE JOURNAL.⁷

Strauss⁷ concludes "The results obtained by the writer lead to only one obvious conclusion, namely, that the so-called Porges-Pollaczek skin test for pregnancy is neither definite nor reliable." Strauss used antuitrin, an extract of the anterior pituitary lobe the nature and potency of which is not known, and a gonadotropic extract of pregnancy urine ("prolan") intracutaneously. This author reviews the work of Porges and Pollaczek and Deutsch.

Dowell⁸ employed a few minims of antuitrin⁹ intradermally. A negative skin reaction indicated pregnancy and a positive skin reaction indicated absence of pregnancy. "This test has been accurate in the author's

hands and in others. It is simple, safe and inexpensive." Dowell made no reference to previous work on this procedure. Dowell writes "My publication was merely a preliminary report and I later found a few (one case to be exact) that it proved to be false, however, all the others were accurate as I remembered it, but the one false one proved to be the one which

prevented me from reporting further on it."⁹ Antuitrin (not to be confused with antuitrin-S) is an unfractionated extract of the anterior pituitary lobe. "The number, nature and potency of the active principles (if any) in such preparations is in general not known. The available evidence indicates that these are usually not assayed but are adjusted to represent a certain weight of fresh or dried gland. Clinical use of products of this type rests on an empirical basis only, their employment should be deprecated."¹⁰ Since this product was employed by Dowell intradermally to determine sensitivity to a gonadotropic principle of the anterior pituitary (according to his hypothesis), the results obtained may be considered without sufficient scientific background to warrant further consideration as evidence of the value of this relatively unknown product as a means of diagnosing pregnancy. In response to a query,¹¹ the question was raised whether

or not Dowell had used a gonadotropic extract of pregnancy urine. Although Dowell does not indicate whether or not he used other extracts in addition to antuitrin, we have assumed that he used the latter throughout his experiments. Grushkin¹² employs a placental extract intradermally which has been heated, thereby destroying the anterior pituitary-like gonadotropic fraction. He reports good results.

Gillfillen and Gregg¹ have by no means developed a "new" intradermal test for pregnancy. They employed 2 minims (0.12 cc) of antuitrin-S² for the test. They "suggested that if a woman contained this substance in

her system, she might not be sensitive to its intradermal application, on the other hand, a nonpregnant woman might show a reaction to its presence." According to their report a positive skin reaction from the intradermal administration of 2 minims of antuitrin-S would indicate absence of pregnancy whereas a negative skin test would indicate pregnancy.

Desiring to repeat the work of these authors, we used¹³ a technic wherein 2 minims of fresh antuitrin-S, which had been stored in a refrigerator, was injected intradermally by means of a 1 cc. all glass tuberculin syringe and 26 gauge needles sterilized by boiling in fresh water. The volar surface of a forearm was first cleansed with a moist alcohol sponge and then wiped with a sponge moistened with physiologic solution of sodium chloride. The latter procedure prevents the reduction of the potency of the antuitrin-S injected by alcohol, although it seems inconceivable that, with reasonable caution the two solutions might be mixed during the injection or following. Many of the tests were read at the end of twenty-four hours. No significant changes were noted. The test was done on both male and female, ward, dispensary and private patients.

The injection itself produces a bleb measuring roughly from 5 to 9 mm in diameter. In reading the test, twenty minutes and one hour after injection, we consider a negative reaction one in which there is no erythema surrounding the bleb. The test is also considered negative when there is redness in the area of from 5 to 9 mm, representing the point of injection. The reaction is considered nonspecific in instances in which there was a faint blush surrounding the bleb, measuring from 10 to 18 mm in diameter. The trauma of injection and the saline solution are probably the cause of this erythema. In those cases in which there was an intense erythema or pseudopods surrounding the point of injection, regardless of size, or in which the erythematous area exceeded 18 mm we considered the reaction indicative of sensitivity to antuitrin-S. In one instance the erythematous area measured 7 cm in diameter.

One hundred and eighteen tests were done on ninety-five females and twenty-three males. Twenty-one women were pregnant. Seventeen cases were postpartum, postabortal or some type of abortion. Six were normal individuals. The remaining seventy-four presented a variety of diagnoses, as noted in the tables. Only eleven individuals yielded a positive reaction (negative test for pregnancy). One of these was a case of incomplete abortion, the others being nonpregnant individuals. There were fifteen nonspecific reactions. The remaining ninety-two patients were insensitive to this substance. These negative reactions, indicative of pregnancy, were obtained in males and females and in pregnant and nonpregnant individuals. The nonspecific reactions occurred in a wide variety of cases.

Our observations would indicate that eleven individuals were nonpregnant and 107 were pregnant. Actually, however, there were only twenty-one pregnancies.

CONCLUSIONS

The results obtained with antuitrin-S injected intradermally in no way exhibit the reliability of this test as a means of diagnosing pregnancy or gynecologic disorders.

13 Dr. E. M. Rotarius of Parke, Davis & Co. gave the authors a generous supply of antuitrin-S.

POSTARSPHENAMINE EXFOLIATIVE DERMATITIS

ETIOLOGY, COMPLICATIONS AND TREATMENT¹

ERVIN EPSTEIN, M.D.

SAN FRANCISCO

Arsenical dermatitis exfoliativa is an entity with which a great deal can be accomplished both by the prophylactic and by the therapeutic approach. For this reason a review of the fifty-nine cases observed at the Los Angeles County Hospital since 1928 is presented. Fortunately, approximately one half of these patients were treated identically by a method based on the principles outlined by Stokes.² The remainder were cared for as individuals according to the methods of various physicians. The cases constituting the two series were similar in all respects. Consequently the statistics of the two are grouped together except in the study of morbidity and mortality.

Only patients with definite exfoliative dermatitis were included. Early lesions that did not develop into the typical edematous desquamative eruption were not considered. Patch tests with neoarsphenamine were strongly positive in all patients on whom such tests were performed. Unfortunately it is impossible to state in most instances which arsenical preparation and which heavy metal was used, for most of the time the patient knew only that he was receiving "arm and hip shots for syphilis."

ETIOLOGY

Paradoxically, heavy metals seem to enact a major role in the production of this form of dermatitis. In only one instance did the patient receive a course of bismuth or mercury compounds before the start of the arsenical course that precipitated the eruption. This patient was started on sulfarsphenamine after a four months rest from antisyphilitic therapy and a crustaceous dermatitis developed after the second injection. This case ended fatally. While nine of the patients presented chancre and an additional eight reported with mucocutaneous secondary eruptions, the remainder had tertiary or latent syphilis. Certainly in the last group, which comprises fully 65 per cent of the patients, a heavy metal preparation prior to the introduction of the arsenical was definitely indicated.

As a second phase of the importance of heavy metals in the causation of this type of eruption, 72 per cent of the patients were receiving both intravenous and intramuscular injections concurrently. This type of treatment has its supporters but, from the point of view of complications at least, seems inferior to the alternating method. At the Los Angeles County Hospital Clinic the alternating method is used, and there has been but one exfoliative dermatitis develop in the last three years (approximately 12,000 arsenical injections). Stokes² points out that intensive use of heavy metals increases the reactivity to arsenicals (32.7 per cent as against 56.3 per cent).

It is interesting to note that in most instances the dermatitis appeared during the initial course of therapy. In 80.3 per cent it was first noted before the twelfth intravenous injection. Two patients had been given twenty-five injections each, while a third received thirty-two injections before the onset of cutaneous complications. The average for the entire group was

1 From the Department of Dermatology and Syphilology, Los Angeles County Hospital.
2 Stokes, J. H. *Modern Clinical Syphilology*, ed. 2. Philadelphia and London: W. B. Saunders Company, 1934.

111 injections. An estimate of the amount of heavy metal given these patients can be ascertained when one considers that, in addition to the arsenic therapy, the average patient received nine intramuscular injections.

While each patient had an average of 15 arsenical treatments after the appearance of the dermatitis, 23 per cent were taken off antisyphilitic therapy as soon as the patient noted cutaneous symptoms. This indicates the necessity of watching for earlier signs of intolerance than the rash or the itching for in almost one fourth of the patients these manifestations indicated a process too far advanced to be aborted by the withdrawal of the causative drug or by the intravenous injection of sodium thiosulfate. However, it is surprising to note that patients apparently possessed of a marked idiosyncrasy to the arsphenamines can often tolerate further therapy during the dermatitis. Two patients received five arsenic treatments each after the appearance of the eruption, while one each was given ten and twenty injections respectively. All four patients survived after receiving the routine therapy.

In fifty patients in whom the source of therapy could be ascertained, twenty-three (46 per cent) were treated in clinics and the remaining twenty-seven by private physicians. A sizable proportion of the latter were treated by osteopaths. This is indeed disappointing to those who feel that the patient with syphilis would be treated more efficiently in clinics than elsewhere. Of course, a county hospital practice includes more people who would frequent clinics than would go to private physicians. The number originating at the former source, however, is astonishing.

This attitude seems justifiable because an analysis of these cases shows that nearly every one followed poor therapy. The following are some of the examples. Sixty-five per cent of the patients should have received a bismuth or mercury preparation before the introduction of arsenical preparations. Eight patients with latent syphilis beyond the age of 45 years, four being older than 60 and one over 70, were started on arsenical therapy without any preparation. Another man, aged 70, was given sulfarsphenamine intramuscularly after a four months rest. Of these, 50 per cent received

had been suffering with a desquamative dermatitis for twenty weeks at home. Obviously, the sooner the proper therapy can be instituted the more favorable the prognosis. This can only mean that either the physician did not diagnose the condition correctly or he did not realize the gravity of this complication. Both are serious errors.

Perivital injections were not of significance in this series. In only one case was a definite history of this error in technique obtainable. Dermatitis exfoliativa occurred more frequently in females than in males, the proportion being 34 to 25. Two of the women were pregnant. The age incidence is given in table 1. The individual ages varied from 19 to 78 years.

TABLE 2—Results of Wassermann and Kahn Tests

Test	Positive	Negative	Doubtful
Wassermann (Kolmer)	20	31	2
Kahn	16	33	4

This complication was seen most frequently in the white race, but examples in Negroes, Filipinos, Japanese and Chinese were also noted.

COMPLICATIONS

The complications encountered did not differ materially in the two series and will therefore be considered together. The most common residual of the dermatitis is scattered patches of chronic eczema. This developed in four cases. Multiple attacks occurred in two cases, one patient suffering two attacks a year for the past six years. In general, the recurrences are not apt to be as severe as the original attack. In two other patients mild relapses developed after the application of multiple patch tests to their backs.

In one case the course was complicated by diphtheria and later by a hemolytic streptococcus septicemia. The patient recovered under the routine therapy plus antitoxins for the complications, but a peculiar reticular fibro-atrophoderma persisted in the V area of the neck.

Multiple furuncles were of such frequent occurrence that they were not considered as complications. It was noted in 96.9 per cent of the thirty-two patients whom I observed. In the external ear, furuncles may cause severe symptoms. Perhaps the intravenous use of dextrose increased the frequency of furuncles in this series.

Laboratory tests were not indicative of severe complicating hepatitis. The van den Bergh reactions, direct and indirect, were negative in the eleven patients tested. Mild urobilinuria was present in four of the seven patients examined. The icterus index was normal in eight and between 10 and 16 in four other cases. All returned to normal within two weeks after hospitalization.

Other examinations revealed a normal blood non-protein nitrogen in seven cases. The blood calcium was slightly lower than usual, ranging from 8 to 9.4 mg per hundred cubic centimeters of blood in seven cases. Arsenic was present in the urine in twelve of fourteen cases (85.7 per cent). Albuminuria was noted in seven (26.9 per cent) of thirty-three patients.

While hardly a complication, serologic changes in the blood might be considered here. The observations in fifty-three syphilitic patients are recorded in table 2.

Far reaching conclusions cannot be drawn from so small a series, but it indicates that the serologic reaction is reversed in about 60 per cent of the cases of exfolia-

TABLE 1—Age Incidence

simultaneous intravenous and intramuscular therapy. As stated previously, 72 per cent of all the patients were on this form of combined therapy.

Two patients received daily intravenous injections. One was also given daily intramuscular treatments. A third patient received twenty-one injections in the arm and hip in the course of five weeks. Another received two intravenous injections weekly.

In one case an early exfoliative dermatitis developed which was diagnosed as a dermatomycosis and treated accordingly. In two instances a crustaceous dermatitis developed following the local application of strong remedies—10 per cent sulfur ointment in one and a combination of ammoniated mercury and iodine in the other.

The average duration of the dermatitis prior to admission to the hospital was 27 weeks. One patient

tive dermatitis In only one was a serologic relapse noted The cerebrospinal fluid was normal in all respects in the seven patients examined, although in two of these blood serologic tests were positive The spinal punctures were done after the eruption had completely subsided This study also suggests that the Wassermann reaction is more likely to be strongly positive after a crustaceous dermatitis than is the Kahn test

TREATMENT

The routine therapy used in thirty-one of these cases was as follows

- 1 One thousand cubic centimeters of 10 per cent dextrose and 35 units of insulin given intravenously daily
- 2 One gram of sodium thiosulfate intravenously every other day for seven doses
- 3 One gram of calcium gluconate orally three times a day, given as much between meals as possible
- 4 Four grams of sodium bicarbonate orally three times a day
- 5 Daily colloid bath
- 6 Various soothing creams and ointments
- 7 A diet high in proteins, fats and vitamins but low in carbohydrates
- 8 Other agents as indicated

The following measures were adopted in the treatment of the twenty-eight control patients

- 1 Only one patient received 10 per cent dextrose although six others received from 25 to 50 cc of 50 per cent dextrose intravenously once a day for varying periods of time
- 2 In general these patients received much more sodium thiosulfate than the 7 Gm given in the first series One patient received 75 Gm, while several were given more than 40 Gm each In only three instances was this drug withheld, one of these patients died
- 3 One and three-tenths grams of calcium lactate was administered three times a day to eleven patients This was given before meals so probably little absorption resulted One patient was given calcium chloride (1 Gm) in the same manner, while one each received 1 Gm of calcium gluconate or chloride intravenously daily
- 4 Only three patients were given sodium bicarbonate and then only to alleviate gastro intestinal complaints Two others received 500 cc of Fischer's solution intravenously as an attempt at alkalization
- 5 Nineteen had daily colloid or soda baths
- 6 The local treatment was too diversified to be discussed here
- 7 Practically all patients were on the general hospital diet, none received the diet previously listed
- 8 Seven were given intramuscular injections of liver extract
- 9 Iodobismitol was administered to one patient who recovered after 196 days in the hospital

In recapitulation, the two series differed in the following respects in series 1 more dextrose, calcium, alkalizing measures, colloid baths and a lower carbohydrate diet were given, in series 2 more sodium thiosulfate and liver extract were given

The rationale underlying the selection of the routine therapy must also be considered The use of dextrose was advocated by Shaffer,³ but he favored the use of hypertonic solutions despite the danger of producing a venous thrombosis The dextrose probably protects the liver by increasing the store of glycogen in the hepatic cells This is believed to aid the detoxifying function of the liver The insulin is given to prevent the excretion of large amounts of dextrose in the urine Personal experiments have proved that 35 units will prevent glycosuria in most patients receiving 1,000 cc

of 10 per cent dextrose intravenously There were no insulin reactions following this therapy except in the presence of severe hepatic damage Furthermore, increases in edema have not been noted, as the fluid seems to act as an efficient diuretic In three cases the dextrose was given rectally because of febrile reactions following its intravenous use

Sodium thiosulfate was introduced by McBride and Dennie⁴ in 1920 Kahn and Loevenhart⁵ have shown that it decreases the excretion of arsenic so that smaller amounts are excreted over a longer period of time This allows the therapeutic agents more time to cope with smaller amounts of the poison Kabilek⁶ states that it decreases allergic tendencies in general, and Shaffer³ states that it is an alkalizing agent This study does not support the claims made for this drug Shelmire, in discussing Shaffer's³ paper, pointed out that sodium thiosulfate is capable of producing an exfoliative dermatitis in patients with an epidermal sensitivity to sulfur Moore⁷ feels that it is probably of no therapeutic value

Calcium therapy was suggested by Spiethoff and Wiesenach⁸ in 1920 Its mode of action is poorly understood but is believed to produce a decrease in sensitivity and exudative tendencies The low blood calcium figures previously quoted add something to the rationale of its employment in arsenical dermatitis

Sodium bicarbonate was used for alkalization, a time-honored method of combating heavy metal toxicity Fischer's solution could be used for the same purpose Baking soda also proved valuable in relieving patients with gastro-intestinal complaints

It was found that the colloid baths added to the patient's comfort Any soothing cream or ointment can be employed locally The low carbohydrate diet was adopted on the suggestion of Craven,⁹ who showed that a high protein and a high fat diet decreased arsenical hepatic complications It was also deemed advisable, as the patients were receiving 100 Gm of dextrose daily by the intravenous route

Liver extract¹⁰ was not included because it did not prove of much help in other types of arsenical poisoning studied In addition, abscesses in the buttocks were too frequently encountered with the intramuscular injection of this agent Calcium thiosulfate was not used, as it did not appear to offer significant advantages over the agents enumerated Cevitamic acid¹¹ was not given a trial, since it was not available at the time this study was being conducted

RESULTS

The patients comprising the two series were similar in every respect Table 3 summarizes the results in regard to time spent in the hospital

If one eliminates the two patients in the control series who remained in the hospital for 196 and 200 days respectively, the average is only 46.6 days for the con-

trol series. However, a considerable difference between the two groups still remains. The fatal cases are not included in these statistics.

Studies of the mortality of both groups indicate that the patients receiving the routine therapy were treated much better than those in the control series. There were five deaths among the twenty-eight patients comprising the second group, while all of the thirty-one in the first series survived.

Other reported series give results similar to those of the control series. Cole and his associates¹² treated sixteen cases with five deaths. Phelps and Washburn¹³

TABLE 3—Days of Hospitalization

	Series 1 Days	Control Days
Shortest time	10	14
Longest time	90	260
Average time	40.5	50.8

had twenty-four cases but five were of the mild type not included in this study. Four of their patients died. It is interesting that all the fatal cases in this series were on simultaneous combined treatment. In addition to the arsenical, one patient each received mercury rubs, mercuric salicylate, metallic bismuth and potassium bismuth tartrate. There was one death due to crustaceous dermatitis for every 1,731 cases of syphilis treated. Of their sixteen severe cases in which details are given, seven were on combined treatment. Cook and Campbell¹⁴ reported two deaths in twenty-four cases. Moore and Keidel¹⁵ reported five deaths in eighteen cases, while Stokes and Cathcart¹⁶ suffered two fatalities in fourteen cases. Shaffer³ had one death in fifteen cases. The mortality for this entire group was 17.9 per cent. The control series had a fatality rate of 17.8 per cent.

An analysis of the fatal cases is also productive of interesting information.

CASE 45—H. A. L., a woman aged 48, Caucasian had secondary syphilis and received an intravenous and an intramuscular injection weekly for ten doses before developing an exfoliative dermatitis. Examination of the urine revealed a trace of albumin. She was treated with a general diet, daily injections of 50 per cent dextrose and sodium thiosulfate, calcium lactate 13 Gm orally three times a day, daily colloid baths, intramuscular liver injections and local therapy. Following the intravenous injection of 50 cc of 50 per cent dextrose, a thrombosis of the right brachial vein developed. She died ten days after admission to the hospital. Autopsy revealed a pulmonary infarction with a secondary bronchopneumonia.

The dermatitis in this case would probably have been prevented if the patient had received only arsenical therapy. The heavy metals probably tend to increase the frequency of arsenical reactions by placing an extra burden on the excretory organs, especially the kidneys. This is more particularly true of mercury than of bismuth. Death was due to thrombosis of a vein with secondary pulmonary embolism, with resulting infarction. This was probably due to the intravenous injection of 50 per cent dextrose, a danger recognized by Shaffer³ in 1934.

16 Stokes J. H. and Cathcart E. P. Contributory Factors in Post-arsphenamine Dermatitis. *Arch. Dermat. & Syph.* 7: 14 (Jan.) 1923.

CASE 48—E. Y., a white woman, aged 37, was given combined therapy because of the accidental discovery of a positive blood serologic reaction. She received four intravenous and four intramuscular injections and a crustaceous dermatitis developed. She was treated at home for six weeks by her private physician and was then hospitalized. She received a high caloric diet, intravenous sodium thiosulfate and local remedies only. A transfusion was given, which precipitated the patient's death.

This patient should have received a heavy metal course prior to the employment of arsenical therapy. The combined therapy was an added insult. The treatment of the exfoliative dermatitis was not adequate in the light of present knowledge. The physician obviously hesitated too long before hospitalizing her. Transfusions are probably contraindicated in exfoliative dermatitis, as it places an extra load on the liver and may prove to be the deciding factor in a subclinical hepatitis developing into a cholemia. This was probably the case in the example of carbarsone poisoning previously reported.¹⁷

CASE 55—P. J., a man, aged 70, Caucasian, had approximately eighteen months of antisyphilitic therapy followed by a four months rest. At the conclusion of this he was given two injections of sulfarsphenamine, and a desquamating edematous erythroderma developed. He was also receiving high voltage roentgen therapy for Hodgkin's disease. Treatment for the dermatitis consisted of a soft diet, local therapy, sodium bicarbonate by mouth and the intravenous injection of sodium thiosulfate. No cause of death was given.

This case constitutes a tragic comedy of errors. A man of 70 years with Hodgkin's disease should never have received antisyphilitic therapy, as the life expectancy in this condition is only about two years. Furthermore, he had already surpassed the average life span, and it is very doubtful whether his positive serologic reaction would ever have caused him any trouble. The use of sulfarsphenamine after a four months rest does not seem to be good medicine either. It is impossible to state with the evidence at hand whether the patient died of his lymphoblastoma or of his dermatitis. The therapy for the arsenical complication was obviously inadequate.

CASE 57—J. H., a white man, aged 26, was given an arsenical intravenously twice a week. After the sixth injection a pruritic eruption appeared, but the physician assured him that it would be "fixed up with a shot of arsphenamine." This was given and a typical dermatitis exfoliativa developed. Treatment consisted of sodium thiosulfate and local remedies. Death was due to bronchopneumonia.

Here one sees the physician's inability to distinguish between a mucocutaneous relapse and an early exfoliative dermatitis. Giving two intravenous injections a week is not accepted technique for the treatment of latent syphilis. Sodium thiosulfate does not constitute sufficient treatment for this serious complication of antisyphilitic therapy.

CASE 59—Mrs. C. G., a white woman, aged 57, was given eight intravenous and four intramuscular injections and a crustaceous dermatitis developed. Treatment consisted of a general diet, calcium lactate by mouth and colloid baths. No cause of death was established.

Case 59 merely reiterates some of the points previously discussed.

CONCLUSIONS

From this study certain conclusions seem justifiable. 1. Postarsphenamine exfoliative dermatitis is preventable in most instances.

17 Epstein Ervin. Toxicity of Carbarsone. *J. A. M. A.* 106: 100 (March 7) 1936.

- 2 Preparation with heavy metals of all patients presenting manifestations other than primary or early secondary lesions would probably decrease the incidence of this complication
 - 3 Simultaneous arsenical and heavy metal therapy is more apt to be complicated by exfoliative dermatitis than is alternating treatment
 - 4 This reaction is most apt to occur during the first course of arsphenamine injections
 - 5 At the appearance of the first cutaneous signs or symptoms, it is often too late to prevent the development of a crustaceous dermatitis
 - 6 The patient should receive immediate hospitalization on the appearance of the dermatitis
 - 7 Dermatitis exfoliativa is most common in white women between the ages of 20 and 40
 - 8 Complications include recurrences furunculosis, chronic eczemas and mild liver and kidney damage
 - 9 The blood serum reaction is reversed in approximately 60 per cent of the cases, the Kahn being more often negative than is the Wassermann reaction
 - 10 The average mortality in this condition is between 17 and 18 per cent
 - 11 The routine therapy outlined in this paper appears to be efficient, and 10 per cent dextrose intravenously seems to be of more importance than sodium thiosulfate and the intramuscular injection of liver extract in the treatment of postarsenical exfoliative dermatitis
- 450 Sutter Street

ACUTE APPENDICITIS IN CHILDREN

PHILIP D ALLEN, M D
NEW YORK

This study of acute appendicitis in childhood is based on 612 cases treated in the Children's Surgical Service at Bellevue Hospital for the ten year period from 1926 to 1935 inclusive. It is made as a sequel to Beekman's¹ report of 145 cases taken from the same service at an earlier date. It includes all children up to the age of 13 years. The final conclusions are based on observations made in our return clinic, where we have observed 475, or 82.4 per cent, of the 576 living patients. These children have been followed for an average of eleven months. No case has been included in this series unless it was pathologically proved to be acute appendicitis.

The cases have been classified as (1) unperforated, (2) abscessed and (3) spreading peritonitis. Cases presenting a question as to which group they belonged have been included in the less serious group.

The method of handling these patients was essentially as follows. All children were operated on as soon as possible after the diagnosis was made. The majority of them received ether anesthesia. The usual incision was a right rectus, this being used in 95 per cent of the cases and the McBurney incision being used in 5 per cent. Until about one year ago a right rectus incision was routine, but at the present time the McBurney incision is preferred. The treatment of the appendiceal stump varied with the condition found and with the individual operator, some preferring a simple ligation while others inverted it. The stump was tied in 350

instances, or 58.59 per cent, while in 237, or 38.78 per cent, it was inverted. In sixteen cases, or 2.6 per cent of the series, the appendix was not removed. These were cases in which abscess formation was so extensive that exploration for the appendix was not considered feasible.

Drainage of the peritoneal cavity was instituted when perforation had taken place or when there was beginning peritoneal inflammation. Drainage was instituted in 408 cases, with drains placed to the peritoneum in

TABLE 1—Distribution and Death Rate of Patients According to Group

	Patients	Percentage	Deaths	Death Rate
Unperforated	314	51	7	2.2%
Abscess	154	25	4	2.6%
Spreading peritonitis	144	24	25	17.4%
Total	612	100	36	5.88%
Infants	72	11.7	11	15.27%
Older children	540	88.3	25	3.9%

forty-seven additional instances. In patients with spreading peritonitis one drain was inserted into the pelvis and one to the region of the appendix, while in those with abscesses one or two drains were inserted into the abscess cavity. The usual drain was the Penrose. The so-called cigaret drain, consisting of a strip of gauze surrounded by a rubber dam, was used in the early part of the series but has been virtually discarded during the last five years. In 194 instances in which it was evident that drainage would be profuse, only the peritoneum was closed, the other layers remaining unsutured. Interrupted chromic sutures were used for the peritoneum and we were always extremely careful to include the transversalis fascia.

Fluids were freely administered postoperatively by hypodermoclysis, although recently venoclysis has been the favored procedure. Blood transfusions were administered to all patients with severe sepsis and to

Chart 1—Increase of appendicitis as the child grows older

those having long continued drainage. Since Wangenstein introduced his suction apparatus, we have used it with great satisfaction both as a treatment and as a prophylactic measure for abdominal distention. Cathartics were not administered postoperatively but enemas were used as indicated.

In this series seventy-two cases, or 11.7 per cent, occurred during the first five years of life. From the age of 5 to 12 years inclusive there were 540 cases, or

Read before the Surgical Section of the New York Academy of Medicine, Dec. 3, 1936.
Dr. Fenwick Beekman, surgeon in charge of the Children's Surgical Service at Bellevue Hospital, gave permission for the reporting of these cases.
¹ Beekman, Fenwick. Acute Appendicitis in Childhood. *Ann. Surg.* 79: 538 (April) 1924.

88.3 per cent. It is interesting to note that Beekman¹ in his 1924 report noted exactly the same age distribution. The youngest patient in this series was 11 months of age and this child recovered. There was a yearly numerical increase, the maximum number occurring in the twelfth year of life (chart 1). The reduced number of cases in the thirteenth year in this series is due to the fact that many children of this age are sent to the adult wards. There was a preponderance of males, a ratio of 3 to 2, or 368 males and 244 females. Of the 612 children, 576 recovered and thirty-six died, a mortality rate of 5.8 per cent. Among the seventy-two children under 5 years of age, sixty-one recovered and eleven died, a mortality rate of 15.2 per cent. Of these eleven deaths, nine were in the spreading peritonitis group. Among the 540 children from 5 to 12 years of age inclusive, there were twenty-five deaths, or a mortality rate of 3.9 per cent. The mortality rate of the males was 6.5 per cent and that of the females was 4.9 per cent. Seventeen children in this group were Negroes, of whom three died, a mortality rate of 17.6 per cent (table 2).

Beekman² reported a mortality rate of 7.58 per cent for all children up to 13 years of age. His infant mortality was 25.6 per cent, while it was 3.9 per cent for the children from 5 to 13. It is to be noted that the mortality has shown a marked decrease for the infants while it is the same in the older children.

A definite seasonal variation was noted, there being a gradual rise in frequency from January to April (chart 2). It remained high during the spring and summer, reaching the peak in August. A marked recession followed for the autumn months. A tendency to the same seasonal incidence is reported by other writers, especially Stone.³ His comment that the peak is reached when acute intestinal infections are common is a feasible explanation for this observation.

Chart 2—Seasonal incidence

The fatal cases averaged 102 hours from the onset of symptoms to the time of operation. The shortest time was eighteen hours and the longest three weeks. By contrast, cases in which survival occurred averaged fifty-three hours from the onset to operation, the shortest being three hours and the longest four weeks. The latter was an abscess case in which recovery occurred.

It is interesting to note that for the first half of this series the average time between the onset and the operation was fifty-nine hours, while it was reduced to forty-seven hours in the last half.

¹ Beekman, Fenwick. Acute Appendicitis in the Infant. *Ann Surg* 80: 911 (Dec.) 1924.
² Stone, C. S., Jr. Acute Appendicitis in Children. *Arch Surg* 30: 3-6 (Feb.) 1935.

UNPERFORATED GROUP

There were 314 cases, or 51.3 per cent, of the series in which the appendix was unperforated at the time of operation. The patients in this group had been ill on an average of thirty-nine hours before operation. Seven deaths occurred in this group, giving a mortality rate of 2.2 per cent. One 3-year-old girl died on the operating table, and this was accepted by the anesthesia department as a death due to anesthesia. Four children died in whom drainage was not instituted and they died within five days of the operation. In two of these there was diffuse peritonitis at autopsy.

TABLE 2—Mortality Rate Comparison of Negroes with Entire Group

	Cases	Percentage	Deaths	Death Rate
Males	368	60	24	6.5%
Females	244	40	12	4.9%
Colored	17	2.7	3	17.6%

One child died of pneumonia on the eighth day, the wound having become diffusely infected on the fifth day. In the fourth case paralytic ileus developed and the patient died on the fifth day. Death occurred on the sixth day in one case in which drainage was done, with a diagnosis of paralytic ileus. One child, an idiot, died twelve hours after operation, apparently of shock.

ABSCESSSES

Of the 154 patients with localized abscess formation, the operation was performed on an average of 152 hours after the onset of symptoms. There were four deaths in this group, giving a mortality rate of 2.59 per cent. All these deaths were in the older group of children. Two apparently died of sepsis. Autopsy in the case of the third revealed numerous pockets in the peritoneal cavity, with a diffuse peritonitis. In the fourth case the autopsy revealed multiple liver abscesses and a subhepatic abscess. The children in whom death occurred lived from twenty-six to seventy-three days after operation.

SPREADING PERITONITIS

In the group in which there was spreading peritonitis there were 144 patients with twenty-five deaths, a mortality rate of 17.4 per cent. Nineteen of these children died from two to forty-eight hours after the operation, apparently from profound toxemia. Two lived four days, one dying of toxemia and one with pneumonia of the left lower lobe. Two others lived five days, in both paralytic ileus developed and in both a jejunostomy was done without benefit. In one boy who lived thirty-five days an intestinal obstruction developed from a band on the thirty-second day. This was relieved by operation. Three days later the child experienced a sudden severe pain in the chest followed by pulmonary edema and sudden death. There was one nonoperative death in this group. This was a boy 4 years of age who had been ill four days on admission. The patient was moribund and obviously too sick for operation. Expectant treatment was instituted but the child died within twenty-one hours. Autopsy in this case revealed a ruptured, gangrenous appendix with approximately 2 liters of pus in the peritoneal cavity. There had been no attempt at localization.

The average stay in the hospital for all patients who recovered was twenty-one days. Children in whom only the peritoneum was sutured averaged thirty days.

in the hospital, while those with the outer layers sutured averaged twenty-one days

This study shows a direct relation between the length of illness and hospitalization. Those sick one day or less averaged seventeen days. For each additional day of sickness there were approximately three extra days of hospitalization, so that those who were sick six or more days averaged thirty-one and a half days in the hospital.

COMPLICATIONS

Of the 156 cases in which drainage was not done there were forty wound infections, an infection rate of 25.6 per cent. There were seven additional instances in which the abdominal layers were closed down to the drain and it was necessary to remove the stitches within forty-eight hours because of marked retention of pus in the abdominal wall. Vomiting that persisted for two or more days occurred in fifty-six cases. Fecal fistula occurred in ten cases, in nine of which recovery occurred.

Disruption of the abdominal wound occurred in four children, all of whom recovered. Two of these were children 4 and 10 years of age. In both cases there had been no drainage and the disruption made itself evident in both instances on the seventh day, or

TABLE 3—*Reduced Hernia Incidence in Patients in Whom Only the Peritoneum was Sutured*

	Cases	Followed	Hernias	Percentage
Only the peritoneum sutured	194	171	5	2.9
All layers sutured to drain	214	176	7	3.9
Closed without drain	165	128	1	0.7
Total	576	475	13	2.7

just after the skin sutures had been removed. The other two disruptions occurred in boys 7 and 11 years of age, one twenty-four and one forty-eight hours after operation. In these two instances only the peritoneum had been sutured. In one, occurring in twenty-four hours, an untied continuous suture lay free in the wound. The other, occurring in forty-eight hours, was a case in which there had been persistent distention, in this case an intestinal obstruction developed on the sixth day, necessitating a jejunostomy. Later a ventral hernia developed, which was successfully repaired.

Retention of pus in the pelvis was noted in twenty-one instances during convalescence. Twenty of these patients recovered, there being but one death in this group. Retention of pus occurring between loops of intestine or deep in the wound occurred in ten instances. All of these patients recovered with expectant treatment.

The pelvic abscesses were treated conservatively with hot rectal irrigations twice daily in Fowler's position and with hot stupes to the abdomen. Most of them drained from the original abdominal sinus. At least three ruptured spontaneously into the rectum and one into the vagina.

Postoperative pneumonia occurred in twenty-six cases, with but three deaths assignable to this cause. Empyema occurred in two instances, in both of which recovery occurred. One of these cases of empyema was preceded by a subphrenic abscess.

Jaundice was noted in three patients in whom there was long continued drainage, and all recovered.

A secondary hemorrhage occurred on the seventh postoperative day in one girl aged 11 years. In this

case the abdomen had been drained through a right rectus incision and apparently the hemorrhage came from an erosion of a large vessel deep in the wound. The hemorrhage was controlled by packing. A ventral hernia developed, which was successfully operated on fourteen months later.

HERNIAS

Among the 475 children seen in our follow-up clinic, thirteen incisional hernias occurred, a percentage of 2.7 (table 3). All but one of these occurred in cases in which drainage had been instituted. Of the 194 patients in whom only the peritoneum was closed we followed 171 and found five hernias, a percentage of 2.9. Of the 214 patients in whom the peritoneum, muscle, fascia and skin were closed down to the drain, we followed 176 and found seven hernias, or a percentage of 3.9. It is to be noted that the latter group gave a 1 per cent higher hernia rate than those patients in whom only the peritoneum was closed. Nine of these hernias have since been operated on and apparently cured. In four instances the parents either refused operation or the children were subsequently lost from the clinic. The patients in whom hernias developed were almost invariably those with prolonged convalescence. In only two was recovery apparently uneventful. Persistent vomiting, pelvic abscess, fecal fistula and abnormally prolonged drainage was the usual story. The average stay in the hospital for this group of children was thirty-five days.

Of the sixteen children from whom the appendix was not removed, twelve lived. In two of these abscesses developed in the region of the appendix six months and four years later. These were again drained and in neither instance was the appendix seen. One child returned for elective appendectomy after one year although there had been no symptoms during the interval.

SYMPTOMATOLOGY

The usual history was that of sudden onset with severe generalized abdominal pain or epigastric pain followed in a short time by vomiting. In two or three hours the pain localized in the lower right quadrant. This course of events occurred in 267 instances, or 44 per cent of the series. In 136 instances, or 22 per cent, the pain remained generalized while in 204 children, or 32 per cent, the pain started and remained in the lower right quadrant. Patients in the spreading peritonitis group showed a greater tendency to have their pain remain generalized.

Vomiting occurred in 485 cases, or 79 per cent of the group. One hundred and twenty-seven children, or 21 per cent, did not vomit at any time during their illness. In only forty-two instances, or 6.8 per cent of the series, was vomiting the first symptom. Frequently vomiting followed the administration of a cathartic. The vomiting generally occurred during the first twenty-four hours of the illness and ceased thereafter.

Marked anorexia occurred in the greater majority. A history of previous as well as immediate constipation was obtained in 163, or 27 per cent, of the series. Diarrhea occurred in thirty-six, or 6 per cent, of the children. It is questionable whether some of these so-called diarrheas did not follow catharsis. One hundred and ninety-three, or 31 per cent, of the charts noted regular bowel habits, while in 220 instances no data on this subject could be elicited.

It is commonly felt that in children an acute appendicitis is frequently preceded by some respiratory infection. This was found to be true in 198 children, or 177 per cent, of this series.

That many children are brought to the hospital only after several attacks was borne out by this study. Twenty-two per cent of the histories revealed one or more previous similar attacks. This was stated not to have occurred in 64 per cent, while in 14 per cent of the charts no mention was made regarding this subject.

CATHARTICS

It was found that cathartics had been administered to 57 per cent of the children in the perforated group, while in the unperforated group 42 per cent had received cathartics. Information as to catharsis was missing in 32 per cent of the charts. Twelve per cent of the patients had received enemas. In only 5 per cent of the cases was it stated that catharsis had not occurred. Of those receiving purgatives, many children had had two or more. The usual agents were castor oil and solution of magnesium citrate.

Examination of this group of children revealed most of them lying with their thighs flexed on the abdomen. The unperforated group most generally showed localized tenderness with rebound tenderness but rarely true rigidity. Generalized muscle spasm was more likely to be found in the young children.

The abscess group usually presented a definite local tenderness, frequently with rigidity. The children with spreading peritonitis were almost invariably tender throughout with local rigidity, and frequently rigidity was generalized.

Masses were felt in eighteen patients by abdominal palpation alone and in thirty-nine instances on rectal examination. In twelve additional instances, masses were felt both abdominally and rectally. Most of these showed localized abscesses at operation. Little attention was paid to tenderness on rectal examination, as we feel that in the absence of a mass such examination should be considered negative in a small child.

Chart 3—Mortality rate in percentage according to year of age

The temperature was invariably elevated, the mean temperature in the unperforated group being 100.7 F, while it was 101.3 and 101.5 respectively in the abscessed and spreading peritonitis groups. The pulse rate was likewise accelerated. Blood counts revealed an average of 14,600 in the unperforated group, 18,000 in the abscess group and still higher, or 19,700 in the spreading peritonitis group. Polymorphonuclears averaged 83.8 per cent in the simple group and were slightly higher in the cases presenting more extensive

pathologic changes. Respiration rates averaged 24 in the unperforated group, 25 in the abscess and 26 in those with peritonitis.

Exact figures as to the frequency of errors in diagnosis is not available for this paper. Mesenteric lymphadenitis, pneumonia and pneumococcal peritonitis in the order named are the conditions most frequently mistaken for appendicitis. It is safe to assume that

Chart 4—Increase in death rate with increase of length of illness

these mistakes are less frequent in a service limited to children than in a general surgical service. To show that the diagnosis is difficult, and especially among infants, I will relate the following case, which is not included in this series.

M. C., aged 10 days, was admitted to the Children's Surgical Service Aug. 23, 1934, with a diagnosis of complete harelip and cleft palate. The child was operated on two weeks later for a repair of the harelip. The lip failed to unite, so that two weeks later the infant was again operated on. Within twelve hours after operation a temperature of 103.4 F, with rapid respirations and cyanosis, developed. Pneumonia was suspected, although it was not positively diagnosed. The child was treated symptomatically for four days, being seen frequently by members of both the medical and surgical staffs. On the fourth postoperative day the child suddenly died. Autopsy revealed an appendiceal abscess in which the appendix had entirely sloughed away. The abscess apparently had recently ruptured, producing a diffuse peritonitis.

COMMENT

The study carried out in this group of cases emphasizes the old and oft repeated observation that, to reduce the mortality of acute appendicitis, operation must be performed soon after the onset of symptoms. This study shows that prolonged illness before operation increases mortality (chart 4) and morbidity and prolongs hospitalization. The high death rate from spreading peritonitis in the young infant makes early operation especially imperative in this group. The mortality rate of 15.2 per cent in infants compares favorably with the mortality rate of 25.6 per cent noted in Beekman's 1924 report taken from the same service. While this would tend to show that patients were being brought to the hospital earlier and perhaps that our treatment is more efficient, the mortality could be reduced further by still earlier operation in this group of children.

From a perusal of the records in this series and from having observed these children in the hospital, an impression is gained that children over 5 and adults suffering from appendicitis present essentially the same history and physical manifestations. It is the younger group that calls for special attention. While vomiting may be given as the first symptom, it is likely that in most cases the child had been previously suffering from pain. The frequent use of cathartics adminis-

tered by the mother and all too frequently by the family physician undoubtedly increases and hastens the progress of the disease

The infant's lack of resistance to infection and the lack of sufficient omentum to wall off the process makes early operation necessary if one is going to prevent spreading peritonitis with its high mortality

The procedure whereby only the peritoneum is sutured in cases in which it is apparent that drainage is going to be profuse should be especially emphasized. This series shows definitely that the incidence of hernia is lower in this group. It is true that hospitalization was long. The two most common objections are, first, danger of disruption and, second, wide ugly scars. Neither is a valid argument. It is true that two of the four disruptions reported in this study came from among this group of cases. Both occurred when this procedure was first introduced and before we insisted on using interrupted sutures, with care being taken to include the transversalis fascia. It is to be noted that the other two instances of disruption occurred in clean cases in which the wound had been closed without drainage. The second objection, that scars are wide, is also invalid. If proper dressings are employed in these cases and the skin edges are drawn together with adhesive plaster as soon as drainage subsides and all protruding granulations are removed below the surface of the skin, these children will present hair line scars when discharged. The great advantage of this procedure is that destruction of tissue of the abdominal wall is prevented and drainage is facilitated.

The high percentage of infections in wounds closed without drainage in this series is to be deplored. It is accepted that the peritoneum will withstand greater contamination than the abdominal wall. It is also true that the abdominal wall of children is less resistant to contamination than that of the adult. More extensive use of a small rubber dam drain down to the peritoneum in these borderline cases should prevent this frequent infection. These drains may be left for about forty-eight hours, thus providing egress for serum, a culture medium for bacteria. This procedure does not delay convalescence, as these wounds heal practically as if drainage had not been employed.

SUMMARY

Acute appendicitis in children becomes more frequent with each additional year of age. It is comparatively infrequent in the child under 5. The relatively high death rate in the infant is due to the frequency of spreading peritonitis, to which the infant offers little resistance. Cathartics undoubtedly hasten perforation. The death rate increases with the length of illness before operation. Hospitalization likewise lengthens with delay in operation. Suturing of only the peritoneum in cases in which drainage is expected to be profuse prevents sloughing of the fascia and muscles of the abdominal wall, provides more adequate drainage and decreases the incidence of hernia. This report reveals a marked diminution in the infant death rate since the last report from the same service.

LEFT HEART ARTERIAL AIR EMBOLISM

REPORT OF A CASE FOLLOWING PNEUMOTHORAX

W E B HALL M D ST JOSEPH MO

In contradistinction to venous embolism, arterial embolism is relatively rare. For this reason and because of other unusual features, a report is made of a case of tuberculosis treated by incomplete thoracoplasty and repeated pneumothoraces, the last terminating fatally. Postmortem examination revealed generalized arterial air embolism.

REPORT OF CASE

History—A white man, aged 24, in the summer of 1932 submitted to repeated pneumothoraces for active left apical tuberculosis. Since little improvement was shown, a first stage thoracoplasty was performed in November 1933. Recovery was retarded and painful, and the patient refused to undergo the second stage of the operation. Pneumothoraces were then continued, the disease appeared to be arrested and weight and strength returned. The man was itinerant, and roentgenograms and fluoroscopic checks were not made for the injections of air given when ever they were requested by the patient. The size of the cavity appeared to have decreased gradually, rarely taking more than from 50 to 200 cc of air in the last six months.

Nov 20, 1936, pneumothorax was performed at the usual site by an office assistant. During the injection the patient went into a type of collapse associated with symptoms not unlike those of cerebral hemorrhage, with nystagmus and strabismus. The amount injected was estimated by the assistant as 100 cc of air. With the collapse, as much air as possible was promptly allowed to escape by the needle, and after first aid administration the patient was rushed to the hospital, where he complained vaguely of some chest pain before lapsing into complete unconsciousness. Breathing was free and easy, although there was pronounced cyanosis and collapsed pulse. Death occurred thirty minutes after the pneumothorax, postmortem examination was performed ninety minutes later. Unfortunately examination of the head was not permitted.

Autopsy—The body was that of a young, well developed and well nourished man which gave the appearance of excellent health. Postmortem rigidity was developing. There was considerable cyanosis, particularly marked on the lips, finger nails and toe nails. Petechiae were not observed. A small unhealed puncture wound was seen in the fourth interspace in the mid-axillary line. There was a long old paraspinal scar, the result of the old thoracoplasty.

The body was opened by routine incision. Several old firm fibrous adhesions were present in the right pleural cavity and there was a slight mediastinal shift to the left. The right lung was not unusual. The left pleural cavity was carefully approached and disclosed a complete fibrous pleural obliteration except for a narrow cavity in the left axillary line measuring 10 by 3.8 cm, still containing a small amount of air and some bright red blood. The capacity of this cavity could hardly have exceeded 30 cc. The puncture wound of the chest was located in a raw area, 3 by 3.5 cm, in the center of the cavity and close to some adhesive bands that bridged the space. The apposing lung surface was torn. The injected air apparently had caused a portion of lung to tear loose from an anchoring adhesive band. On pressure of the lungs, blood and air bubbles, coming apparently from a ruptured vessel, were forced readily into the cavity. There was nonunion of the portions of ribs involved in the thoracoplasty, particularly the third and fourth ribs. In the upper part of the chest the lateral wall came within from 5 to 7 cm of the spine. In the gutter produced, the lung was firmly fixed. Exploration of that portion disclosed a posterior apical tuberculous cavity measuring approximately 7 by 3 by 2.5 cm, filled with granular, necrotic, yellowish, semi-liquid material. The lung in general was displaced posteriorly, rarely appearing anterior to the middle to the anterior axillary line. The rest of the chest space was made up by mediastinal shift and the pleural adhesions.

The heart lay intact in a smooth, glistening, pericardial sac. There was a slight amount of blood-stained pericardial fluid. The epicardium was smooth and glistening. The left ventricle was firmly contracted, while the auricles, particularly the right one, showed moderate dilatation. The myocardium muscle tissue was dark purplish red, firm, uniform and well proportioned. No thrombi were noted in the chambers. The valves were smooth and intact. Some dark clot was present in the various chambers. Bright red, frothy blood was found around the aortic valve but more particularly under the mitral valve. The gas bubbles measured from 0.2 to 0.8 cm in diameter. There was no definite occlusion of the coronary orifices. Close examination of the distal branches, however, disclosed, even prior to removal and with the aorta intact, a very prominent beading effect due to innumerable very fine bubbles in the blood stream. On stripping, these bubbles could be readily moved along the vessel channels and subsequently were milked back into the coronary orifices. No epicardial or endocardial ecchymoses were encountered.

All other structures and organs presented an appearance of acute asphyxia, having assumed a very profound purplish or dusky color. Hemorrhage or ecchymosis was not noted. Exploration of the arterial system disclosed blockage or filling of the branches by bubbles of air combined with dark, frothy blood. This was noted in the hepatic, renal, splenic and superior mesenteric arteries and the celiac axis. Beading was distinct in the mesenteric vessels. Exploration was not continued into the extremities.

Microscopic examination of the tissue of the left lung showed marked pulmonary atelectasis together with extensive fibrosis, scarring and production of large caseating abscesses and smaller miliary inflammatory points, associated with typical tuberculous tissue reaction as well as frequent giant-cell formation of Langhans type. This involvement appeared not only in the lung parenchyma but also intimately in the walls of the bronchioles, some of which showed complete ulceration of the mucosa. The inflammation appeared to be in an active state. Myocardial sections showed little tendency toward either degeneration or inflammation. Blood vessels varied from dilated to collapsed forms and were often associated with moderate acute interstitial hemorrhagic infiltration of noninflammatory, degenerative or infectious origin. Kidney sections showed a well developed combination of amyloid change, chronic glomerulonephritis and acute glomerulonephritis of septicemic type, together with a very pronounced congestion both of the occasional glomerular capillaries and of the more frequent interstitial capillaries, associated in the latter with occasional interstitial hemorrhage.

Summary Diagnosis.—The diagnosis was old first stage left thoracoplasty, chronic obliterative fibrous pleuritis, left mediastinal shift, caseating tuberculous abscess of the apex of the left lung, rupture of the adhesion in the pneumothorax due to artificial pneumothorax with secondary tear-laceration of lung pleura and secondary rupture of the pulmonary vessel resulting in left traumatic bronchopleural fistula and air embolism of the pulmonary vein, left hemopneumothorax. Hemorrhagic pericardial effusion, right auricular dilatation, air embolism of the left heart chambers, air embolism of coronary arteries, generalized arterial air embolism with acute congestion and cyanosis of asphyxia. Chronic glomerulonephritis, amyloidosis of kidney.

COMMENT

It has been shown experimentally by Hall and Ettinger¹ that the lethal insult threshold of the lung in thrombotic embolism is very high, degrees of occlusion being tolerated short of complete stoppage of blood flow through the pulmonary arteries. This is chiefly because of the tremendous vascular bed and secondary bronchiolar arterial blood supply in the lung. In the case of arterial embolism, however, one is dealing essentially with a totally different combination of factors involving two very vital organs with inadequate collateral circulations to take care of any acute vascular occlusion, particularly when one considers a massive embolic shower. Thus even a very small amount of air, if not quickly absorbed by the erythrocytes and blood stream, may in its short passage from the lung and through

the heart find lodgment in the coronary vessels. A similar condition must be presumed as effective in the case of the brain. Although the oxygen element in a vascular air embolus is almost instantaneously absorbed, the nitrogen tends to remain intact except for its reduction into the finer frothy foam that lodges about the valves and in the various smaller branches of the arterial system, which lack a mechanism for absorption and disposal of excess gases, such as is present in the lungs. The present case was one of tissue asphyxia due to embolic filling of the smaller vessels. This, in the case of the heart, produced the characteristic anginal pain of coronary occlusion complained of by the patient.

The autopsy showed the inadequacy of an incomplete thoracoplasty in producing quiescence of a tuberculous lesion. It is to be regretted that the patient was allowed to have his way, refusing the second stage of the operation and resorting to pneumothorax. It would appear that a constant check by roentgenograms and fluoroscopic examinations should be made in artificial pneumothoraces as to the size and effects of the pleural collapse and the presence of adhesions. Continued pneumothoraces in small cavities, with the major pleural space obliterated by adhesions, hardly can be expected to produce a therapeutic response. When the available pleural space is known to be considerably reduced and adhesions are probable, it would seem that further pneumothoraces should be performed fluoroscopically under direct supervision of the responsible operator. The manometer should be carefully watched for rapid increase or reduction in pressures, and the amount of air in the reservoir available for injection, or the amount of air injected, rarely should exceed that of the previous injection.

In the present case an amount of air greater than the available pleural space was injected into a pleural cavity bridged by a line of fusion of lung to the parietal wall or into the adhesion itself. In either case a segment of lung was forced from its former covering and in the process produced a traumatic bronchopleural fistula, accompanied by exposure and rupture of an underlying pulmonary vessel. The distention of the cavity by the injected air has subsequently resulted in an increasing stretching and enlargement of the rupture point in the vessel wall, allowing a ready avenue for aspiration and escape of air resulting in the arterial air embolism. Once embolism has occurred, all possible injected air should be withdrawn by disconnecting the needle or by actual aspiration. If, however, air emboli have already gained access to vital organs the insult tolerance of which toward vascular occlusion is low, as in the case of the heart, the prognosis immediately becomes grave. The case should then be treated in the same manner as though solid emboli had gained access to the involved organ or organs. Mild sedatives and heavy oxygen therapy become absolutely mandatory to aid tissues suffering widespread asphyxia.

SUMMARY

1 A case of air embolism of the arterial system originated in rupture of a pleural adhesion as the result of artificial pneumothorax.

2 Air emboli, froth and bubbles were found in the chambers of the left side of the heart, under the mitral valve, about the aortic valves and in the sinuses of Valsalva, the coronary arteries, the celiac axis, the splenic, renal, hepatic and mesenteric arteries and presumably the cerebral arteries.

3 Coronary embolism was accompanied by anginal symptoms similar to those of ordinary coronary occlusion.

4 Death occurred within thirty minutes and was due primarily to myocardial asphyxia resulting from filling of the coronary vessels with gaseous bloody froth or asphyxia of cerebral centers of similar etiology.

5 Insult tolerance of vital organs to arterial occlusion, as in air embolism, is much lower than the tolerance of the lungs in venous embolism.

6 The fatal element in air embolism is nitrogen, which is absorbed slowly in the blood, persisting in the form of frothy bubbles long after the oxygen portion, which is rapidly absorbed.

7 Primary first stage thoracoplasty is an inadequate operation for pulmonary collapse and immobilization in tuberculosis.

8 Pneumothoraces should be performed under responsible supervision with repeated checks by roentgenograms and fluoroscopic examinations.

BILATERAL TRILOBECTOMY

THE REPORT OF A SUCCESSFUL CASE

RICHARD H. OVERHOLT, M.D. BOSTON

Bilateral lobectomy for bronchiectasis has seldom been attempted. Eloesser,¹ Edwards² and Lewis³ have each reported a case. In the series of surgically treated bronchiectasis patients of Churchill,⁴ four successful bilateral operations were done. These few reports would indicate that surgical extirpation of lobes from both the right and left lungs has been considered even more difficult of attainment than the removal of all the pulmonary tissue on one side. However, bronchiectasis is found in far greater frequency in both lower lobes or in the left lower

Fig 1—Bronchogram (retouched) showing marked sacculations of the bronchi of the lower lobes. Note the triangular basilar shadows indicative of atelectasis. Also note the clearness of the lung fields above the triangular shadows which space is filled entirely by the upper lobes.

and right middle lobe than it is found to be limited to the upper and lower lobes on the same side. Therefore in the treatment of this disease the thoracic surgeon will in the future be asked to consider bilateral lobectomy more often than pneumonectomy.

The following case, in which the right middle, right lower and left lower lobes were successfully resected, is of interest from two points of view. 1 The three lobes in which the bronchiectasis was found were totally atelectatic. The entire respiratory burden was carried by the two upper lobes. Compensatory emphysema had taken place in these two lobes and they practically filled the entire thorax. 2 Lung volume studies made before and after operation demonstrated that the removal of the three atelectatic lobes did not greatly alter the respiratory reserve of the patient.

History—Miss S. C., aged 19, referred by Dr. N. R. Pillsbury, superintendent of the Norfolk County Hospital, was admitted to the New England Deaconess Hospital May 13, 1935. The patient had had pneumonia when 3 years of age and since that time there had been a chronic cough, variable amounts of expectoration, frequently streaked with blood, and occasionally a frank pulmonary hemorrhage. The breath had a fetid odor. There was slight dyspnea on exertion. The latter two factors definitely had limited the patient's physical and social activities. There had been no recent weight loss. The remainder of the medical history was irrelevant.

Examination—The patient was a pale, slender girl of normal height for her age of 19 years. The digits showed marked clubbing but no cyanosis of the nail beds. There was no deformity of the chest and its expansion was equal. The excursions of the lower ribs were, however, slightly restricted on both sides. The percussion note was resonant throughout

except over both bases posteriorly near the vertebra. Coarse rales and accentuated breath sounds could be heard over this area. The action of the heart was normal except for a rate of 96. The blood pressure was 138 systolic, 80 diastolic. The temperature was 98.6 F. The remainder of the physical examination was negative.

Laboratory Examination—Roentgenograms of the chest revealed triangular shadows at both bases. The lung markings in the area above the triangular shadows were less dense than normal. Iodized oil, instilled intrabronchially, outlined sacculations within the triangular shadows (fig 1). The right middle and lower and left lower lobes were involved in the process and the upper lobes showed compensatory emphysema and practically filled the entire thorax. The sputum was characteristic and measured between 8 and 9 ounces (235-265 cc) daily. All other laboratory studies were within normal limits except the leukocyte count, which was 12,000. The study of the vital

Vital Capacity and Lung Volume

8 months after removal of left lower lobe	11/13/36	1 162	1 950	20

* All estimations are given in cubic centimeters.

capacity and of the lung volume (functional residual air) was made by the Christie method.⁵ The results are shown in the accompanying table.

Operative Notes—1 First stage right lower and middle lobectomy was done June 1. Intratracheal cyclopropane anesthesia was administered by Dr. U. H. Eversole. The pleural cavity was opened in the periosteal bed of the resected eighth rib and the wound enlarged by dividing the seventh and ninth ribs posteriorly. The middle and lower lobes were found to be contracted, airless and completely atelectatic. These two lobes were mobilized, the inferior pulmonary ligaments were divided as far up as the hilus and the fissure was separated. The upper lobe was wiped with dry gauze, reinflated and the chest closed.

The convalescence was uneventful and the patient was discharged on the fifteenth day. Within ten weeks' time the cough and expectoration decreased approximately 25 per cent.

2 First stage left lower lobectomy was done September 27. The same anesthesia was employed. The left side of the chest was opened and the lower lobe found to be completely atelectatic. The upper lobe practically filled the entire chest. The lower lobe

Fig 2—Bronchogram made by injecting the drainage tube with iodized oil three weeks after the last operation. Note the wide ramifications of the bronchi of the remaining upper lobes. Iodized oil can be seen in the stumps of the lower bronchi.

was mobilized, the upper lobe wiped with gauze and reexpanded, and the chest closed. The convalescence was uneventful, the patient was discharged on the thirteenth postoperative day. Within the next month the amount of expectoration continued to decrease and then averaged 4 ounces (120 cc) a day, about one-half the usual preoperative amount.

3 Second stage right, middle and lower lobectomy was done November 13. The incision was made in the scar of the previous operation and the right side of the thorax was opened after resection of the seventh rib, the sixth divided posteriorly and the scar below. All three lobes were adherent throughout. The lower and middle lobes were mobilized. Transfixion ligatures of catgut were placed in the hilus, the needle being passed through the bronchus. A Nelson-Roberts tourniquet containing No. 2 chromic catgut was applied. Multiple catgut sutures were placed in the stump after the two lobes had been excised. The tourniquet was then disengaged, leaving the catgut strands to be tied around the stump as a mass ligature. A catheter drain was introduced through a stab wound 2 inches below the lobectomy incision. The upper lobe was reinflated and the chest closed. The convalescence was uneventful. The patient was discharged on the thirty-second postoperative day. During the next three months, improvement was continuous. The amount of expectoration was reduced to 3 ounces (90 cc) daily.

4 Second stage left lobectomy was done March 3, 1936, by means of the same technic as employed in the previous stage, the left lower lobe was removed. The postoperative period was not remarkable. Iodized oil injected in the drainage tube three weeks after operation outlined the entire tracheobronchial tree on the roentgenogram (fig. 2). The patient left the hospital

Fig. 3—Appearance of patient eight months after the last operation. Note the absence of deformity and the good nutritional state of the patient.

on the thirty-third postoperative day greatly improved. The drain was removed May 13 and the wound was healed a week later.

Follow-up examinations have been made at regular intervals and the patient was last seen nine months after the last of her series of operations. There has been a marked improvement in the general appearance of the patient (fig. 3). Coughing spells and expectoration have been reduced by 90 per cent and the clubbing of the digits has definitely receded. The patient volunteers that she is now able to lead a normal social life. She also reports that she can climb three flights of stairs without becoming short of breath.

A lung volume estimation was made Nov. 13, 1936, eight months after the last operation. The following measurements were made: (1) complementary air 961 cc., (2) reserve air 201 cc., (3) residual air 1,749 cc., (4) total capacity 2,911 cc. (sum of 1, 2 and 3), (5) vital capacity 1,162 cc. (sum of 1 and 2), (6) lung volume 1,950 cc. (sum of 2 and 3), (7) tidal air 400 cc.

COMMENT

The patient was a chronic pulmonary invalid and had been so for sixteen of her nineteen years of life. The three bronchiectatic and atelectatic lobes were functionless and a source of great potential danger. The surgical extirpation of these

abnormal lobes made it possible for the patient to enjoy ordinary physical and social activities. The danger of progression of the disease has been materially lessened. Measurements of the lung volume and of the vital capacity after operation gave higher values than those found preoperatively. These determinations show quite convincingly that the lobes which were removed were functionless. The study also suggests that the remaining upper lobes were better able to function when relieved of the burden of the other three disease-ridden lobes.

605 Commonwealth Avenue

Therapeutics

THE THERAPY OF THE COOK COUNTY HOSPITAL

EDITED BY BERNARD FANTUS, MD
CHICAGO

NOTE—In their elaboration, these articles are submitted to the members of the attending staff of the Cook County Hospital by the director of therapeutics, Dr. Bernard Fantus. The views expressed by various members are incorporated in the final draft for publication. The articles will be continued from time to time in these columns. When completed, the series will be published in book form.—Ed

BLOOD PRESERVATION

This preliminary report on the establishment of a "blood bank" at the Cook County Hospital is perhaps justified by the interest displayed in this development, the inquiries received from various parts of the country, and the importance of the promptest and most generous exchange of experience in a new field of life-saving endeavor.

That blood can be preserved for weeks in condition fit for transfusion is now a well established fact, thanks most especially to Yudin's¹ work on cadaver blood. There is, however, something revolting to Anglo-Saxon susceptibilities in the proposal of using cadaver blood and it is not probable, even were this not the case, that enough blood could be secured in this manner to be of great practical importance. The "blood bank" proposition, on the other hand, seems susceptible of extensive development and it is to this, most especially, that we desire to call attention.

The first question that comes to the mind of any one in connection with blood preservation is: Where does one get the blood? At Cook County Hospital we have experienced no difficulty on this score by following simple rules promulgated by the medical staff of the hospital. The necessity for these rules is obvious. Just as one cannot draw money from a bank unless one has deposited some, so the blood preservation department cannot supply blood unless as much comes in as goes out. The term "blood bank" is not a mere metaphor.

NOTICE TO MEDICAL STAFF

"Hereafter an effort will be made to preserve by refrigeration blood to be used for blood transfusions. This method should accomplish two things: first, it should make blood available at any time it is needed; second, it should make the process of blood transfusion much more simple.

"It is obvious that one cannot obtain blood unless one has deposited blood. Staff physicians may deposit blood

¹ Yudin, S. S. Transfusion of Cadaver Blood. J. A. M. A. 106: 997 (March 21) 1936.

for credit at any time. A record will be kept of all blood credited to each service.

"Depositing Blood"—Staff physicians will obtain from the Solutions Laboratory chilled 500 cc flasks, which will contain 70 cc of 2.5 per cent sodium citrate solution. These flasks carry two test tubes for the collection of 5 cc of whole blood in each for the purpose of typing and for the Wassermann test. The blood will be drawn into the flask in the usual manner and taken immediately to the Solutions Laboratory. The date, the name of the donor, his address, his color, the name of the intern and his service should accompany the flask. By means of this system only one donor needs to be bled and he need not be typed, which greatly lessens the trouble occasioned by transfusion.

"Keeping of the Blood"—In the laboratory the technician at once files it away in the refrigerator, which must maintain a constant temperature between 4 and 6 C, types it, tests it for sterility and the absence of syphilis, and credits it to the service that furnished the blood.

"Drawing on the 'Blood Bank'"—Assuming that a patient needs blood transfusion, the house physician should secure from the patient 5 cc of blood, type it, and make out a requisition in proper form for the quantity and type of blood needed, which will be delivered to him from the refrigerator. It should be warmed by placing it in a water bath, the temperature of which would not feel too hot for the hand, and used immediately after warming.

"Cross-Matching Before Injecting"—The blood thus secured should be cross-matched with the patient's blood by the resident who supervises blood transfusion. Not only should the corpuscles to be injected be matched against the patient's serum, but the serum to be injected should be matched against the patient's corpuscles. Owing to the possibility of serious allergic reactions, the blood of a patient allergic to horse serum should not be injected into a patient who recently had a horse serum injection. Repeated transfusions in which the same donor is used may give rise to anaphylactic shock.

"Administration"—While the hasty injection of blood may produce speedy death from 'speed shock,' the slow injection—literally drop by drop—has no such danger, even in disease conditions of the heart or lungs. Throughout the injection the patient should be carefully observed for any unfavorable reaction. The early and characteristic symptoms are 'uneasiness' in the chest, difficulty in breathing, excruciating pain in the back, and nausea. Failure to recognize these early symptoms may be responsible for a fatal result. Fall in blood pressure and impaired heart action because of insufficient return of venous blood to the right side of the heart with resulting cyanosis, dyspnea and anuria dominate the picture. These symptoms are believed to be due to the liberation of 'histaminoid' bodies from the breaking down of red blood corpuscles, which lead to dilatation of the venous capillaries and spasm of the peripheral arterioles. Embolic closure of the finest pulmonary and renal vessels may also contribute to the clinical picture. It is claimed that the best remedy for this reaction is the immediate infusion of compatible blood.

"Dosage"—Overloading of the circulation must be avoided. In infants 20 cc of blood per kilogram of body weight should not be exceeded. In adults, after hemorrhage, the amount of blood required depends on

the quantity lost. The loss of from 2,000 to 2,500 cc of blood may be fatal and the giving of 1,000 cc of blood may save life in such a case. To increase coagulability of the blood, e. g., in hemophilia, a transfusion of 250 cc suffices."

SOURCES OF BLOOD

The main source of blood will no doubt always be the healthy volunteer donor, whose service should be enlisted whenever possible. No matter what type blood the donor furnishes, the blood is sent to the laboratory, where it is exchanged for blood of the type desired. The advantage of the "blood bank" over the previous method is obvious. Only one donor needs to be bled, which dispenses with the commotion occasioned by calling to the hospital a horde of excited relatives before a suitable donor can be found.

A second source of blood is from patients with cardiac decompensation and those with excessive elevation of blood pressure, provided the patient is not suffering from infection, uremia or other toxemia. It should be a rule that practically all patients in need of digitalis should have a preliminary abstraction of blood to unload the heart before stimulating it.

A third source of blood is the antepartum clinic. Here the blood bank function of this project expresses itself most simply. We deposit in a bank money we do not at the moment need, to be able to draw on it when we do need it. In the same way a pregnant woman can easily spare a little blood a week or two before her expected confinement to have it saved for her against the time she may need it during or right after parturition. If she does not need this blood, it should become available for any one who does.

There are some who seem to be in particular need of this antepartum blood. It is the premature child. Some pediatricians seem to be convinced that a premature infant who is not doing well is much benefited by the intramuscular injection every other day of 5 to 10 cc of blood of a woman who carries a child under her heart.

Now it so happens that the pediatric clinic can furnish blood to the bank also. When a mother brings a sick child to the hospital, it is of great advantage to that child to be given from 10 to 20 cc of the mother's blood injected intramuscularly—10 cc in each gluteal region. This will secure passive immunization against measles and most other contagious diseases to which the child may be exposed while in the hospital. In this manner the specter of cross-infection ever present may be largely banished from a children's hospital. There is no reason why a healthy woman might not easily spare, and without greater inconvenience, 120 cc instead of 20 cc of blood and have the other 100 cc preserved in the bank in case her child needs it and, if it does not, she should permit this blood to save the life of some other child.

A patient who is to have an elective surgical operation could do no better than to deposit a week or two before the ordeal a pint of blood in the bank to have it available in case it is needed during or after the operation.

The bank may also function in the way of "lending" blood. Any one who owes his life to blood transfusion clearly owes some blood to some one else who is in great need of this restorative. This is eminently the case with convalescents from infectious diseases. In streptococcal sepsis, for instance, as well as in scarlet fever and probably also in influenza and many other

infectious diseases, the blood of the convalescent is curative to the victim of the same kind of infection. It should be the plain duty of the one who has recovered from such a disease to donate some of his blood to save the life of a fellow man in the hour of his desperate need. Surely one whose life has thus been saved owes some of his now curative blood to another victim of the same kind of infection. Opsonic index determinations on the preserved blood might permit one to predict in what kind of infection the convalescent's blood would be particularly serviceable.

A SERUM CENTER

The limit of blood preservation is lysis of the red blood corpuscles after their death. Obviously the trick of blood preservation is to compel blood corpuscles to enter a "hibernation" stage so that, life processes being at a low ebb, they may continue to live for a much longer time than they otherwise would. The survival period of blood thus preserved seems to be from three to four weeks. It is entirely probable that intensive research, which should at once be undertaken, may extend somewhat this blood corpuscle survival period. But sooner or later hemolysis sets in. With the appearance of the first traces of hemolysis the serum should be separated from the blood and the serum preserved—as it easily can be—for as long a time as may be necessary.

This will not only furnish a liberal supply of the so much needed human convalescent's serum, but also of normal human serum with its natural immunizing and other therapeutic properties. In shock, for instance, when there has been but little or no hemorrhage, compatible human serum should be much more valuable than the 6 per cent acacia solution now advocated for the purpose. In extensive burns in which shock and the loss of blood serum from profuse exudation are the cause of the circulation depression that may be fatal, the intravenous injection of blood serum is much more rational than that of blood, because these patients usually have an excess of red blood corpuscles per cubic millimeter. In certain hemorrhagic conditions, blood serum may furnish the lacking principles, even though in thrombopenic purpura nothing but transfusion of fresh blood may serve the purpose.

CONTRAINDICATIONS

As blood transfusion is a trying, even dangerous, procedure to the recipient, the indications for it should be drawn strictly and rather narrowly. We have kept statistics for the year preceding inauguration of the blood preservation service and found that death has occurred in about one third of the number of patients in whom transfusion has been done. We hope to better these statistics with the new method. The deaths cannot, of course, be charged to blood transfusion but must be ascribed to the fact that too many antemortem transfusions are being done in this hospital. Unless there is some extraordinary reason for postponing the inevitable end, blood transfusion is not justified in hopeless conditions. The physician's desire to do everything possible for the patient committed to his charge must not lead him to prolong the agony of the dying by major therapeutic efforts.

"In the treatment of sepsis," says Bock,² "it is possible to waste more blood than for any other condition. Severe anemia due to sepsis is an indication for blood

transfusion, but sepsis per se without evidence of anemia is not." Immunotransfusion is, of course, an entirely different matter.

In leukemia, in the anemia of Hodgkin's disease, and in primary anemias with the exception of pernicious anemia, and then only under special circumstances, blood transfusion is inadvisable. It is also contraindicated by pulmonary edema, myocarditis and nephritis.

INDICATIONS

Dangerous hemorrhage and shock are the two most important indications for blood transfusion. Transfusions are probably used more in surgical shock than in hemorrhage.

In rapid profuse hemorrhage, a drop in blood pressure soon sets in. It is this drop of pressure that causes the syncope of such hemorrhage. The blood count does not alter to any great extent until sufficient fluids have entered the blood stream to dilute the blood. A person may suddenly bleed to death and the blood count and hemoglobin percentage remain almost normal. It takes from twelve to twenty-four hours for dilution to occur. So a drop in blood pressure and an elevated pulse rate are the significant factors in the first few hours of severe bleeding.

In case of a slow hemorrhage, on the other hand, the blood pressure may be well maintained, and then a fall in hemoglobin percentage to 50 or below or a rise of the pulse rate to 120 or more indicates that blood transfusion should be undertaken promptly. Blood pressure estimation furnishes, in slow bleeding, no indications of any value, as the pressure is well maintained by vasoconstriction until profound sudden shock supervenes on failure of this mechanism.

"Next to ligature," says Bock, "blood transfusion is the most effective means we have to insure cessation of hemorrhage." When the hemorrhage is of the inaccessible variety, as well as in hemorrhagic diseases, such as hemophilia and purpura hemorrhagica, small (250 cc.) and repeated blood transfusions give better results than a large transfusion.

In preparation for surgical procedures, all markedly anemic patients require blood transfusion. Indeed, before or after any extensive or prolonged operation blood transfusion is of value. In heroic conditions, massive blood transfusion is called for. In grave trauma demanding amputation, 500 cc. of blood given at intervals of half an hour before, during and after the operation may save a life. In profuse hematemeses, continuous drip blood transfusion at the rate of from 90 to 150 cc. an hour may transform, in two or three days, a patient apparently moribund into a good surgical risk. Operation performed immediately after such hemorrhage is usually fatal.

In severe cases of pernicious anemia, blood transfusion is indicated during that critical period of a week, more or less, required for liver therapy to become effective.

In jaundiced patients, small blood transfusions before, during and after operation will minimize the oozing of blood that may be fatal.

Other indications, such as immunotransfusion and possible food function of blood, require definition better than we now possess.

CONCLUSION

This statement of the aims and means of the blood preservation service is primarily intended to secure the better cooperation of the staff of this hospital.

² Bock, A. V. The Use and Abuse of Blood Transfusions. New England J. Med. 215: 421 (Sept. 3) 1936.

Dr Lindon Seed is chairman of a Committee on Blood Transfusion, which consists of a representative of each one of the special services at the hospital, and all matters pertaining to this work should be referred to this committee

We have had enough experience at Cook County Hospital to say that the use of properly preserved blood is safe and efficient

We also know that extensive cooperative investigation will be required to develop this method as rapidly as seems mandatory to save lives now unnecessarily lost

It is this need, as well as the desirability of better financial support for so important a project, that has dictated this preliminary publication

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION
OF THE FOLLOWING REPORTS HOWARD A. CARTER, Secretary

COLLENS-WILENSKY INTERMITTENT VENOUS OCCLUSION APPARATUS

Preliminary Report

Manufacturer U M A, Inc, 11 East Forty-Eighth Street, New York.

This device is designed for the treatment of peripheral vascular diseases of the extremities. In the opinion of the firm, its use is indicated in such conditions as thromboangitis obliterans, vascular sclerosis, indolent ulcer and gangrene

The apparatus consists of a motor-driven pump which supplies air to a pneumatic cuff. Pressure of this device is regulated by means of a pressure-measuring indicator. A pressure of from 40 to 90 mm of mercury is imposed on the proximal portion of the diseased extremity and results in a restriction of the returning venous blood. It is claimed that the pressure is applied up to a level which does not interfere with arterial filling

A suitable timing mechanism is incorporated in the device, which maintains a pressure for two minutes, after which a release valve is actuated electrically to cause an automatic deflation of the cuff. The promoters claim that during the release period an increased arterial flow through the extremities occurs, giving rise to the following effects in the treatment of organic peripheral vascular obstruction: (1) relief of pain, (2) increase of skin temperature of extremity, (3) increase in walking efficiency, (4) increase in vascularity, permitting amputation at lower levels, and (5) healing of chronic indolent ulcers associated with vascular obstruction

This apparatus was placed in a clinic acceptable to the Council. The investigator reported that

1 From a mechanical standpoint, the performance of this machine is entirely satisfactory. The duration and amount of pressure are controlled automatically and may be thus adjusted to the requirements of the individual patient. During three months of constant use, the machine required no repair, no adjustment. Often cuffs do not fit the patient's thigh, but this objection could be easily remedied

2 From the physiologic standpoint, the production of an intermittent venous hyperemia to increase peripheral circulation seems sound and tests performed indicate that both surface temperatures and the oscillometric curves increase after the application of this method. During venous occlusion there is a filling and stretching of the venocapillary bed, while during release a reactive hyperemia takes place, bringing about vasodilatation. There is, however, no provision made in this type of treatment to empty the vascular bed effectively and for this reason a certain amount of continuous venous stasis exists. This method is to be used only with great caution

While the evidence submitted is favorable to the therapeutic employment of this device, the Council does not believe that the evidence is strong enough to warrant acceptance at this time but believes the manufacturer should be given more time to gather additional data and submit it. When such information is available, the Council will again give the product careful consideration

EMERSON INFANT RESPIRATOR ACCEPTABLE

Manufacturer J H Emerson, 22 Cottage Park Avenue, Cambridge, Mass

The Emerson Infant Respirator is designed for administering artificial resuscitation of new-born babies whose respiration is delayed or is of poor quality. It will provide continuous artificial respiration over extended periods of time. This unit is hand operated. The device is cylindric, about 17 inches long and 12 inches in diameter. At one end is a diaphragm connected to a lever which may be moved back and forth to create positive and negative pressure within the chamber. At the other end is a soft rubber collar through which the infant's head protrudes. Electrically operated infant respirators were reported on in THE JOURNAL, May 2, 1936, page 1563

Certain advantages were noted in the construction of the respirator. Its compactness combined with its light weight favors portability. Manual operation of the respiratory chamber is an advantage, as it places the rate and magnitude of respiratory diaphragm excursions under complete control of the operator. The pneumometer registers the positive and negative pressure exerted on the body of the infant. The transparency of the respiratory chamber permits visibility of the child's movements and color, thus allowing for adequate determination of progress in resuscitation. The clamps used to attach the head piece to the chamber allow rapid assembly for action. The neck piece of sponge rubber may be cleaned. All parts seem durable

This unit was placed for investigation in a clinic acceptable to the Council. It was used in cases of respiratory lags, such as narcosis from sedation given during delivery, asphyxia from aspirated amniotic fluid and intracranial damage

In using this respirator, the investigators found that certain procedures were necessary for optimal performance. First, the respiratory passages of the infant must be thoroughly cleared of foreign material such as blood and amniotic fluid. This may be done with a sterile ear syringe, if the trachea is not blocked, or with a tracheal catheter if it is. The removal of obstructions is of great importance, as failure to do so may result in the aspiration of the offending material into the bronchial tree. The interior of the respiratory chamber should be heated by some means, as the carrier of the infant is too cold without this preparation. In the trials by the Council investigator, a hot water bottle was covered and placed on the carrier during delivery to allow adequate time for the chamber to become warm and was left on the carrier during use to keep the baby warm

The radially arranged straps used to control the size of the opening in the collar through which the infant's head protrudes from the respirator are of value in enlarging the aperture during passage of the child's head. Their purpose, apparently, is to prevent the collars fitting the neck too snugly during resuscitation. In some instances sufficient air passed beside the neck to prevent the chamber from working as a closed unit, thereby destroying the ability of the system to create positive and negative pressure. On the other hand without an attempt to control the size of the collar about the baby's neck, constriction of the neck occurs with collapse of the trachea. In the opinion of the Council such a pressure placed on the carotid and jugular vessels is not of benefit to the child, particularly in cases of intracranial hemorrhage, because the increased pressure thus caused may add to the severity of the complications

Emerson Infant Respirator

During the course of the forced respiratory excursions, it is found necessary in normal or large infants to insert a tongue blade over the tongue to open a passage for the air. In small and premature infants a tracheal catheter has invariably to be inserted to prevent tracheal collapse by compression from the collar about the baby's neck.

It is found advantageous during its use to administer by mask or intra-oral tube a mixture of 95 per cent oxygen and 5 per cent carbon dioxide.

The flap-valve on the side of the chamber was found to be of no practical advantage and the respirator was observed to function best when the valve was kept closed. Such a device might be useful in a mechanically motivated chamber, but where manual control is exercised at all times its presence seemed superfluous.

Employment of the respirator is of advantage in cases of narcosis in which respirations are delayed for an appreciable period of time, when its use is supplemented by the use of a tongue blade or tracheal catheter and carbon dioxide and oxygen mixture, as described. It may also be used in deep asphyxia from obstruction after the latter has been removed. It is not felt to be advisable in cases of difficult delivery in which intracranial damage may have been done, first, because the added manipulation of the child during the placing of its head through the collar is not in line with proper treatment of cranial injury, and, secondly, because of probable alteration in intracranial pressure and impediment to circulation by the collar, which would be strongly contraindicated.

The respirator has a field of usefulness in cases in which it may be necessary to give artificial respirations over a protracted period of time. Its advantage in acute cases of short duration is doubtful. It does not appear to decrease the period of time when artificial respiration is needed, but it does make such treatment physically much easier for the operator, as well as allow for better control of rate and depth of respiratory excursions.

In view of the foregoing report, the Council on Physical Therapy voted to include the Emerson Infant Respirator in its list of accepted devices.

Council on Pharmacy and Chemistry

REPORT OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT
PAUL NICHOLAS LEECH Secretary

CONDOL AND ERTRON NOT ACCEPTABLE FOR N N R

ConDol and Ertron are marketed by the National Institute of Nutrition and the Nutrition Research Laboratories, Inc., respectively, as preparations of irradiated ergosterol of very high potency, mainly for use in the treatment of arthritis. In advertising booklets issued by the firms concerned, Ertron is claimed to be "a highly concentrated form of vitamin D, prepared by a newly developed process which employs ergosterol as its raw material. It is biologically standardized and supplied in semi-solid form, in gelatin capsules, each capsule containing not less than 50,000 U S P units of vitamin D." ConDol is declared to be "a high grade source of vitamin D—particularly designed for use in the Reed technique in the treatment of arthritis. The method of preparation is by the Campsie process which is the irradiation of ergosterol in high quality Oil of Sesame at a filtered wave length of 2,536 Angstrom's units." Neither product has been submitted by its manufacturer for consideration of the Council. The numerous inquiries received, however, have prompted the Council to consider these products on its own initiative.

The advertising sent to the Council's files by physicians for ConDol is comparatively conservative, merely proposing the use of the product for the treatment of arthritis, according to the suggestions of Drejer and Reed of the University of Illi-

nois. The advertising for Ertron is much more flamboyant. The following paragraph taken from a recently received circular is typical:

"Widespread use has demonstrated the clinical efficacy of Ertron in arthritis. It may be relied upon to produce beneficial changes in every type of the disease, regardless of the stage of its advancement. Affected joints become smaller, periarticular swellings diminish, interosseous muscles relax and lose their spasticity, mobility gradually increases and frequently becomes normal. Pain is lessened relatively early in the treatment, and finally disappears entirely. Psychic and systemic improvement keeps pace with the regression of the disease, the appetite is increased, anemia is overcome, lost muscular strength returns, the patient gains weight, and the general outlook becomes hopeful and optimistic."

Soon after the appearance of the work of Drejer and Reed (*Arch Phys Therapy* 16 537 [Sept.] 1935) the Council considered the question of the use of viosterol (irradiated ergosterol) preparations of high potency in the treatment of arthritis, and decided that there was not sufficient evidence to warrant the acceptance of such preparations for inclusion in N N R. The Council calls to the attention of physicians the fact that there is no proof that such large doses of vitamin D are not toxic.

The Council notes that, whereas a number of firms have been enthusiastically exploiting high potency viosterol preparations, the Wisconsin Alumni Research Foundation desisted from entering this field. The Council desires to commend the Foundation for this evidence of its conservative attitude on this question.

As time went on and exploitation of products such as Ertron and ConDol became more widespread, the Council asked a consultant to investigate the present status of this therapy. The consultant presented the following summary:

VITAMIN D AND ARTHRITIS

In the evaluation of any type of therapy for almost any organic disease, probably the least satisfactory criterion is subjective improvement as estimated by the patient.¹ This is especially true when the disease for which treatment is given is a chronic one with natural periods of varying severity of symptoms. One condition that falls definitely into this category is chronic arthritis. It is fair, therefore, on the basis of probability alone, to expect as a result of the treatment of a series of cases of chronic arthritis, by any method whatsoever, that a certain number of the patients will be reported clinically improved and some, temporarily at least, completely relieved of symptoms, especially pain. Recently reports² have appeared to claim clinical improvement of chronic arthritis as a result of the use of massive doses of vitamin D. This has given some of the manufacturers of concentrates of vitamin D or activated preparations of high potency an opportunity to exploit their products on the basis of scientific medical backing for their claims. In these reports, however, the percentage of cases in which clinical improvement occurred was in no instance greater than has been reported for a similar series of cases of chronic arthritis treated by vaccines and various other methods.³ In the reports the estimate of improvement is based almost entirely on the statements of the patient and in none is there corresponding roentgenographic or other convincing objective evidence of the improvement claimed or admitted by the patient.

Critical examination of the reports on the value of vitamin D in the treatment of chronic arthritis reveals little to warrant the belief that the beneficial effects claimed are specific. As suggested by the authors of one of the reports cited, a conservative attitude toward this means of therapy is desirable.

The Council, after consideration of the consultant's report and of the available information concerning Ertron and Con-Dol, declared these products unacceptable for inclusion in New and Nonofficial Remedies for lack of evidence for their claimed therapeutic value, and deprecates the unwarranted exploitation of these products to the medical profession

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION

PAUL NICHOLAS LEECH Secretary

MERCURIN—A mixture of 20 per cent of the β -methoxy- γ -hydroxymercuri-propylamide of trimethyl cyclopentane dicar-

boxylic acid $\text{C}(\text{CH}_3)_2\text{C}(\text{CH}_3)\text{COOHCHCHCHCONHCHCHCHCH}_2\text{CHHgOH}$ and 80 per cent of its sodium salt. Mercurin is a complex synthetic mercurial containing about 40 per cent of mercury prepared from d camphoric acid and a racemic substituted propylamide

Actions and Uses—Mercurin is proposed for use as a diuretic to be administered rectally. Its potency is comparable to that of parenterally administered mercurial diuretics. It is well tolerated. It is contraindicated in advanced chronic nephritis and acute renal disease and should be used with caution in the presence of diarrhea, enterocolitis and hemorrhoids or other rectal disorders. It probably acts as a mild renal irritant.

Dosage—Mercurin is supplied in the form of cocoa butter suppositories, each containing 0.5 Gm of mercurin, to be administered rectally in the morning, repeated at three to five day intervals as required by each individual case.

Manufactured by Chino Chemical and Pharmaceutical Works Ltd. Budapest Hungary (Campbell Products Inc. New York distributor). U. S. patent applied for U. S. trademark 338 989.

Mercurin Suppositories 0.5 Gm

Mercurin occurs as a white odorless bitter tasting noncrystalline powder that is very slightly soluble in water, soluble in alcohol and insoluble in ether. An aqueous solution has a pH of about 7.8. Suspend about 1 Gm of mercurin in 10 cc of water, add 30 cc of 2 normal acetic acid and 1.5 Gm of ammonium chloride, heat on the water bath and bubble hydrogen sulfide through the solution until no more precipitate is formed, filter while hot and place the filtrate in the refrigerator for twelve hours, filter and wash the crystals with a little cold water and dry at 75°C. The precipitate with hydrogen sulfide indicates the presence of mercury; the crystals melt at from 157.5 to 158.5°C and are identified as trimethyl cyclopentane dicarboxylic acid monoallylamide. Transfer about 1 Gm of mercurin accurately weighed to a 25 cc standard flask, add 1 cc of sodium hydroxide solution, fill to the mark with water, observe the rotation of the resulting solution within thirty minutes in a layer 200 mm thick at 25°C using the D line of sodium. $[\alpha]_D^{25}$ is not less than 9.5 nor more than 10.5.

Saturate with hydrogen sulfide 5 cc of the solution prepared for observing the rotation, no precipitate forms and no coloration results (Heavy metals—especially mercuric ions). Dissolve 0.1 Gm in 5 cc of water, add 1 cc of diluted nitric acid, filter through paper and divide the filtrate into two portions, to one portion add 1 cc of silver nitrate solution, no more than a slight opalescence results (chlorides); to the other portion add 1 cc of barium nitrate solution, no turbidity results (sulfates). When tested for arsenic according to the U. S. Pharmacopeia X, the product meets the requirements for arsenic (p. 428 Arsenic Test).

Transfer about 0.5 Gm of mercurin accurately weighed to a wide mouth weighing bottle and dry to constant weight in an oven at 80°C. The loss in weight is not less than 6.5 per cent nor more than 7.5 per cent. Determine nitrogen by the micro Dumas method; the nitrogen is not less than 2.75 per cent nor more than 2.80 per cent when calculated to the dried substance. Transfer an accurately weighed specimen of the original to a platinum dish and ash in the presence of sulfuric acid, ignite to constant weight in a muffle furnace at 900°C. The residue calculated as sodium sulfate is equivalent to not less than 4.20 per cent nor more than 4.70 per cent sodium when calculated to the dried substance. Transfer about 0.3 Gm of mercurin accurately weighed to a large platinum dish, add 15 cc of a solution of sodium sulfide (made by dissolving 50 Gm of crystallized sodium sulfide to make 100 cc of solution) and sufficient water to nearly fill the dish, electrolyze at 5 volts for eighteen hours, siphon off the solution while adding water until the ammeter shows that no current is flowing, break the circuit, wash the mercury deposit with alcohol and ether, dry for a few minutes in a warm place and then in a desiccator over sulfuric acid in which a beaker containing mercury has been placed, weigh the percentage of mercury is between 30.2 per cent and 40.2 per cent when calculated to the dry basis.

MERCURIN SUPPOSITORIES

Place a suppository in a beaker containing 150 cc of cold anhydrous ether. When disintegration is complete, transfer the undissolved material to a prepared gossamer crucible using the first filtrate as needed to complete the transfer, dry the crucible in an oven at 80°C, cool in a desiccator and weigh; the weight of the insoluble material is not less than 0.47 Gm or more than 0.53 Gm and it meets the standards for mercurin.

Council on Foods

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COUNCIL ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION AND WILL BE LISTED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED

FRANKLIN C. BING Secretary

STOKELY'S STRAINED LIVER SOUP

Manufacturer—Stokely Brothers & Company, Indianapolis

Description—Canned, strained liver soup to which is added potatoes, water, carrots, tomato juice, barley and rice flours, celery and salt. The natural minerals and vitamins have been largely retained.

Manufacture—Selected carrots and potatoes are washed, peeled, mixed with finely cut cleaned celery and strained in an atmosphere of steam. Fresh beef livers are cooked, cut and strained. Formula proportions of the ingredients are mixed, heated to 98°C without exposure to air and filled into enamel-lined cans, which are sealed and processed for sixty-five minutes at 116°C.

Analysis (submitted by manufacturer)—Moisture 84.3%, total solids 15.7%, ash 2.3%, sodium chloride (NaCl) 1.8%, fat (ether extract) 0.5%, protein (N \times 6.25) 3.8%, crude fiber 0.9%, carbohydrates other than crude fiber (by difference) 8.2%, reducing sugar as dextrose 1.2%, sucrose 0.6%, total acidity as maleic acid none, alkalinity of ash, cc normal acid/Gm 2.3, pH 5.5.

Calories—0.53 per gram, 15 per ounce

Vitamins—The natural vitamin content is retained in large measure in the manufacturing process by the use of equipment and procedure that exclude incorporation of air; the vegetable material is exposed to steam only.

Claims of Manufacturer—A supplementary food for infants, seasoned to bring out full flavor and packed in enamel-lined cans, useful in the feeding of children and adults on soft diets, because of smooth consistency and bulk without roughness. Retains in high degree the natural flavor, mineral and vitamin values of the raw products. Requires only warming for serving.

(1) SEXTON BRAND HAWAIIAN PINEAPPLE CRUSHED, JUICE PACKED

(2) SEXTON BRAND HAWAIIAN PINEAPPLE SLICED, JUICE PACKED

Distributor—John Sexton & Company, Chicago

Packer—Alexander & Baldwin, Ltd., Honolulu, Hawaii

Description—(1) Crushed pineapple packed in juice. (2) Sliced pineapple packed in juice.

Manufacture—Essentially the same as Hawaiian Cross Brand Hawaiian Pineapple (THE JOURNAL, April 13, 1935, p. 1331, and June 8, 1935, p. 2097).

Analyses (submitted by manufacturer)—(Analyses of entire contents, including liquid)

	(1)	(2)
Moisture	83.1%	83.7%
Total solids	16.9	16.3
Ash	0.3	0.4
Fat (ether extract)	trace	trace
Protein (N \times 6.25)	0.6	0.4
Crude fiber	0.4	0.3
Carbohydrates other than crude fiber (by difference)	15.6	15.2

Calories—(1) 0.64 per gram, 18 per ounce, (2) 0.62 per gram, 18 per ounce

Claims of Manufacturer—For diets in which sweetened fruit is proscribed.

GLENDORA BRAND TOMATO JUICE

Distributor—Glendora Products Company, Warren, Pa.

Packer—North East Preserving Works, Inc., North East, Pa.

Description—Tomato juice containing in high degree the natural vitamin values. Seasoned with salt. The same as North East Brand Tomato Juice (THE JOURNAL, Feb. 20, 1937, p. 641).

SATURDAY, JULY 10, 1937

THE CLINICIAN AND THE SEROLOGIC TEST FOR SYPHILIS

The results of the two studies of the American Committee on Evaluation of Serodiagnostic Tests for Syphilis suggest certain definite alterations in American medical practice. The proper person to interpret serologic results is not the serologist, who is usually not in contact with the patient. The clinician can fit laboratory data with history and physical appearances. The serologist can report only the objective result of a physicochemical test, the clinician must determine what that result means.

Every clinician who uses the serologic tests for syphilis should assure himself that (a) the laboratory employed is under the direction of a competently trained serologist, that (b) intralaboratory check of the accuracy of the test in common use is constantly maintained by the performance of another test of approximately equal specificity and sensitivity, e g, a complement fixation test is checked by a flocculation test or vice versa, or a flocculation test checked by a different flocculation test, that (c) interlaboratory checks of the accuracy of the tests employed are periodically carried out by the exchange of specimens with a different laboratory, and that, (d) most important of all, the accuracy of the laboratory is constantly checked against the known clinical diagnoses of the patients from whom specimens are submitted. This implies a close association with a large syphilis clinic.

The ideal serologic test for syphilis is one that is completely specific (which gives no false positive or false doubtful results in known nonsyphilitic persons). There is no such test. The results of the two American serologic conferences show, however, that a satisfactory test in this respect must give less than 1 per cent of such false positive results and that only three tests in common use in this country—the Kolmer complement fixation test and the Kahn and Kline diagnostic (not the Kahn presumptive or Kline exclusion tests)—qualify under this requirement. Two other flocculation tests, the Eagle and the Hinton, may also qualify after further trial.

All other tests examined in the serologic conferences and in common use in America except the three (or five) named are unsatisfactory from the standpoint of specificity and should not be used by the average diagnostic laboratory. Even with these named tests the clinician must remember that a false positive (or false doubtful) result may be obtained in about one patient out of a hundred tested, and he must be on his guard against diagnosing syphilis when it is not present and instituting treatment that is not needed.

The ideal serologic test is one that is so sensitive as always to detect syphilis when it is present. There is no such test. To the clinician, moreover, specificity is more important than sensitivity. He must remember that, in the laboratory, sensitivity is usually gained at the expense of specificity as any test is adjusted to give the highest possible proportion of positive results in known syphilitic patients there is a hand in hand increase in the proportion of false positive results in nonsyphilitic patients. However, the five tests named in the preceding paragraph—Kolmer, Kahn and Kline diagnostic, Eagle and Hinton—compare favorably with any known tests as to sensitivity in that they are successful in detecting from 70 to 90 per cent of positive and doubtful results in a known syphilitic population (treated and untreated). The percentage sensitivity in the hands of the originators of these tests is: Kolmer 72.6, Kahn diagnostic 82.3, Eagle 82.6, Kline diagnostic 86 and Hinton 90.

The archaic and confusing system of reporting by plus marks is so confusing that its abandonment has begun to be frequently suggested. Many nonsyphilitic patients have been treated for syphilis on the basis that a test reported as "one plus" means positive, when as a matter of fact it may not mean any such thing. For the plus marks the words "positive," "doubtful" and "negative" should be substituted without qualifying symbols or adjectives.

Many laboratories still perform a complement fixation test with several antigens, e g, plain alcoholic, cholesterinized or acetone insoluble, or check a complement fixation with a flocculation test or one flocculation test with another. While this type of multiple testing is desirable for intralaboratory check, the reporting of such multiple results to the clinician is often confusing. When a blood specimen gives a negative result with, for example, the Kolmer test but a positive result with the Kahn, this signifies only (a) that the patient has but a small quantity of reagin in his blood and (b) that the Kahn test is more sensitive than the Kolmer. The same thing applies to different antigens in the complement fixation test.

If the history is positive and physical signs are present, a single positive test may be accepted. If these are absent, the positive result must always be verified by a repeat test in the same or a different laboratory before the patient is told of the diagnosis or treatment started.

This is in order to guard against the possibility of false positive results in nonsyphilitic persons, a chance ranging from 0.1 to 0.5 per cent even with the five tests named, and greater with other tests. The only other diseases or conditions that give a positive serologic test for syphilis are malaria (rarely), yaws, relapsing fever and leprosy (all frequently). In untreated syphilis the range of positivity of the five tests named is from 90 to 95 per cent in all stages of the infection.

Doubtful would mean that there had not been a definite result and that the test should be repeated. False doubtful results in nonsyphilitic persons are more frequent than false positive (from 0.1 to 1 per cent with the five tests enumerated, greater with others). However, a doubtful result may mean syphilis, especially if the patient has been previously treated.

If the tests are negative there is a 95 per cent chance that the patient does not have syphilis (in the absence of previous treatment), but a negative result does not exclude the diagnosis.

The clinician should possess certain minimum information as to the laboratory he employs, the accomplishments and limitations of the test that it uses, and the meaning of simple terms used in reporting. Without this knowledge he cannot expect to treat his syphilitic patients either scientifically or satisfactorily.

HAZARDS OF CONTAMINATED FRUITS AND VEGETABLES

Recently a case of acute lead poisoning as a result of the ingestion of apples from which spray residue had not been completely removed was reported.¹ Only a short time ago another investigator,² who has studied the problem of spray residues on foods extensively, expressed the belief that the potential danger from lead and, to a lesser extent, arsenic poisoning from contaminated fruits and vegetables has not been sufficiently emphasized. Ingested lead accumulates in the viscera and particularly in the bones and is gradually and continuously released. The continued presence and circulation of small amounts of lead throughout the organism may eventually impair health. The onset of symptoms, such as loss of appetite, malaise, loss of body weight, weakness, fatigue on exertion, anemia, gastrointestinal disturbances, pains in the joints and later paralysis, may be so insidious that chronic poisoning by lead-contaminated foods is not at first suspected.

Analyses of cabbage procured from a public market in the southeastern part of the United States showed an arsenic content of from 0.02 to 0.45 grain and of lead from 0.09 to 1.24 grains per pound. From 1 to 2 grains of arsenic may be toxic or even fatal to an adult. It is thus evident that a pound of these par-

ticular cabbages contained from one fourth to one half of a toxic or fatal dose of this element alone. In addition, the amounts of lead present were by no means small. Similar degrees of contamination were found in certain other foods, such as fresh apples, apple pomace, and cauliflower.

The potential hazard from foods contaminated with lead from spray residues is not limited to man but may also affect domestic animals exposed to contaminated feeds, pastures and water supplies. Economic losses in live stock have been so large in some regions where spraying of fruit trees is common that some stock raisers have been obliged to give up their business. Domestic animals known to have been affected include turkeys fed on vegetation in sprayed apple orchards, and horses that have grazed on alfalfa grown between sprayed trees. Cases are also on record of poisoning of live stock from spray residue carried as "drift" to pastures from orchards that have been sprayed from airplanes. One valley in the Pacific Northwest has received as much as 7,000,000 pounds annually of lead arsenate for the past twenty years. Therefore perhaps 50,000 tons of lead arsenate has permanently contaminated the soil of this valley. Some assume that the spray residue is washed away by rains or is blown away by winds, but the evidence available at the present time indicates that this is not the case. Most of the lead arsenate is gradually taken up by the vegetation grown on that soil.

Satisfactory control rests largely on the producer of fruits and vegetables. As has been pointed out,³ stringent laws to control the lead and arsenic content of these foodstuffs intended for interstate commerce should be enacted. The producer should be compelled to remove spray residues as completely as possible, preferably by the hydrochloric acid rinse procedure,³ from the surface of apples and other deciduous fruits intended for intrastate commerce. He should not use the skins of sprayed fruits in the preparation of cider, vinegar, jelly, stock feed or other products. He should never use lead arsenate or other arsenical sprays on vegetables, such as cabbage, cauliflower, Brussels sprouts, broccoli, spinach, kale, celery and snap beans, which are consumed in their entirety. As an added precaution, the consumer should always wash thoroughly before using all fruits and vegetables that may have been exposed to metallic sprays. These measures are at best only palliative, and the only satisfactory permanent solution of the problem is the absolute elimination of dangerous substances as sprays. This, of course, would necessitate the perfection of other insecticides, harmless to man and to domestic animals. According to Hanzlik, "This is actually being done experimentally, and it is not too much to hope that practical success will soon be achieved."

SEX HORMONES AND TUBERCULOSIS

Clinicians of fifty years ago often noted improvement in the symptoms of pulmonary tuberculosis during pregnancy. Some even went so far as to recommend pregnancy as a therapeutic device for tuberculous girls. The alleged beneficial effects of pregnancy in tuberculosis have been tested on laboratory animals. Jameson,¹ Muller, Burke and Bogen, and others report that in their hands pregnancy has had a favorable action in tuberculous guinea-pigs. Other investigators, however, deny this but agree that pregnancy has little or no injurious effects in tuberculous animals.

Since changes in endocrine balance are prominent features of pregnancy, Steinbach and Klein² of the Josiah Macy Jr. Foundation, Columbia University, have tested the possible therapeutic effects of commercially available sex-endocrine products on tuberculous rabbits and guinea-pigs. The preparations thus far tested by them include (1) blood serum of four month pregnant mares, (2) two gonadotropic extracts of human pregnancy urine, (3) anterior pituitary extract and (4) an estrogenic placental extract. While the questionable therapeutic effects observed by them would not at the present time justify clinical trial of these preparations, their experimental method and results are of interest.

These investigators injected male and female rabbits and guinea-pigs subcutaneously with carefully standardized doses of bovine tubercle bacilli. Endocrine therapy was begun on the day of the injection and continued daily (except Sunday) for from six weeks to four months. At varying intervals after the infection, one or more treated animals and an equal number of untreated controls were killed. The severity of the tuberculous infection was estimated from the number, nature and distribution of the lesions in the lungs, kidney, liver, spleen and lymph glands. In groups of tuberculous rabbits and guinea-pigs treated with anterior pituitary extract or with the estrogenic preparation the severity was practically the same as in the controls. Rabbits and guinea-pigs treated with pregnant mare serum or with one of the gonadotropic extracts of pregnancy urine (follutein), however, showed apparently significant therapeutic effects. The most encouraging results, however, were noted in animals treated with a second gonadotropic preparation (antuitrin-S), estimated as about a third of the severity in the untreated controls. Several animals treated with antuitrin-S were without macroscopically demonstrable tuberculous lesions, although a minute focus in a single lymph gland would be found on microscopic examination. Studies of the effects of castration are now in progress in the New York laboratories, to determine whether or not gonadotropic substance acts independently on

the reticulo-endothelial defenses or indirectly through stimulation of the sex glands.

Interesting as these borderline results are from a purely theoretical point of view, there is as yet no convincing evidence that gonadotropic therapy can be of benefit to the tuberculous patient. Until curative rather than apparently prophylactic effects can be demonstrated for tuberculous animals, clinical trial will not seem to be justified.

Current Comment

PHYSIQUE OF YOUNG MEN DURING UNEMPLOYMENT

The effect of unemployment on health is difficult to assess. It must be disassociated from other factors such as malnutrition and original physique (which may have had something to do with the unemployment) and many others. In spite of these difficulties an attempt has recently been made by McKinlay and Walker¹ to estimate the effect of unemployment on the physique. In the course of their routine duties as medical referees they examined a number of unemployed men with a view to gaging their suitability for reception into training centers organized by the Ministry of Labor. Early in this work it became apparent that the collection and analysis of actual measurements of certain physical and physiologic features indicative of the state of nutrition and physical fitness would provide the most satisfactory evidence on which to base conclusions. They consequently set out to determine the differences between men in and out of employment in respect to body weight and height. For this purpose they utilized the records of a consecutive series of 771 unemployed men, the majority of whom had been out of work for prolonged periods. The investigators attempted to eliminate as many of the disturbing factors as possible and were thoroughly cognizant of the inexactitude of their conclusions. The comparisons of the employed and unemployed men from Glasgow and the west of Scotland showed, however, that the unemployed were neither so tall nor so heavy as the employed at the several ages between 18 and 46 years. The deficit was relatively and absolutely greater among the older than among the younger men. Whether these differences were the result of the selective action of unemployment or the different occupational composition of the two groups or of both these factors was not clear. That it is not an adverse effect of unemployment was suggested, however, by the fact that height was as much affected as body weight. When allowance was made for the observed differences in height, the body weight of unemployed men as a whole was not inferior to that of the corresponding group of the employed. From these inquiries, together with the results of an analysis of a fairly extensive but not yet published

¹ Jameson E. M. *Gynecological and Obstetrical Tuberculosis* Philadelphia Lea & Febiger 1935

² Steinbach, M. M. and Klein S. J. *J. Exper. Med.* 65: 205 (Feb) 1937

series of hemoglobin readings, they concluded that the nutritional state of this section of the unemployed population is not at present a cause for more serious concern than is that of employed men of comparable status. The major differences with respect to physical efficiency as revealed in the report by Cathcart and his collaborators suggest the probability of deterioration in other directions and emphasize the importance of extending investigations along numerous lines to other sections of the unemployed and their dependents.

REVISED SHIP QUARANTINE REGULATIONS

February 1, for the first time since the institution of the federal system of maritime quarantine, qualified commercial vessels legally entered a United States port without halting for quarantine inspection.¹ The new ruling allowing this is called "pratique." A wireless message certifying as to the state of health on board the incoming vessel is required, and hence the term "radio pratique" has been adopted to describe the procedure. Although the principle is not new, its application to commercial vessels is new. Only passenger vessels were ever considered for "radio pratique." It has been necessary to investigate world health conditions and, specifically, the eligibility of foreign ports or geographic areas from the standpoint of their sanitary conditions. The qualifications and abilities of all the regularly employed ship's physicians were also investigated. To be eligible, all ships must conform to the following requirements. They must engage principally in the carrying of passengers, the "rat-attractive" and "rat-harboring" items of cargo must be limited to 25 per cent of its dead weight cargo carrying capacity, they must be on regularly scheduled service between New York and certain designated ports, a whole time physician employee of the vessel must be carried as a regular member of the crew, they must visit no port in which a quarantizable disease is known or suspected to have occurred in epidemic proportions within sixty days preceding the visit, no commercial shipments of birds of the parrot family may be carried, and relative freedom from rats must be satisfactorily maintained. A further safeguard is provided by the fact that the medical officer of the Public Health Service who boards the incoming vessel before it reaches the dock himself inspects all persons reported ill by the ship's physician. If no questionable disease is found, the ship may proceed directly to its dock without quarantine inspection. From February 1 to March 26, a period of fifty-four days, a total of 127 vessels had availed themselves of the privilege of "radio pratique." A total of seventy-six different ships of 822,308 net tons belonging to eighteen steamship companies under nine flags were thus passed. These ships carried 42,438 passengers and 48,973 crew members. If this system proves adequate, enormous saving in time and expense will result for the government, passengers and ship owners alike.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

CALIFORNIA

Dinner to Sir Henry and Lady Brackenbury—The San Francisco County Medical Society will sponsor a dinner in honor of Sir Henry and Lady Brackenbury, London, August 14 in San Francisco. Sir Henry is a vice president of the British Medical Association, former chairman of its council and a member of the General Medical Council. He and his wife are en route to a medical meeting in New Zealand at which Sir Henry will represent the British association.

Library Given to University—The medical library of the late Dr. Charles Brooks Brigham, a member of the faculty of the University of California Medical School, San Francisco, for several years, has been given to the university. The collection is said to be a fairly complete history of the progress of medicine in the last three quarters of the nineteenth century. According to the University Clip Sheet, Dr. Brigham is remembered as the physician who in 1898 removed the stomach of a San Francisco woman, who lived seventeen years after the operation. Dr. Langley Porter, now dean of the university medical school, administered the anesthetic to the patient. Dr. Brigham died in 1903. The recent gift to the university includes among other things, the stomach and a description of the operation.

DELAWARE

Fifty Years of Practice—Dr. Robert B. Hopkins, Milton, was guest of honor at a dinner, June 17, given by the Sussex County Medical Society at the Rehoboth Beach Country Club to celebrate his completion of fifty years in the practice of medicine. Dr. John Cooke Hirst, Philadelphia, was the principal speaker. Dr. Hopkins graduated at Jefferson Medical College in 1887. He is 72 years of age.

FLORIDA

New Director of Vital Statistics—Dr. Edward M. L'Engle, Jacksonville, formerly a member of the state board of health, has been appointed registrar of the bureau of vital statistics of the board, succeeding Stewart G. Thompson, Dr. P. H., who resigned to become full time executive secretary of the state medical association. Dr. L'Engle graduated at Johns Hopkins University School of Medicine, Baltimore, in 1902. He is not in practice.

Society News—Dr. Edward Jelks, Jacksonville, president of the Florida Medical Association, addressed the golden jubilee meeting of the Florida State Pharmaceutical Association in St. Petersburg, May 18. At a meeting of the De Soto-Hardee-Highlands County Medical Society in Wauchula, May 11, Dr. Nathaniel L. Spengler, Tampa, spoke on "The Economic Status of Medicine." A symposium on arthritis was presented before the Duval County Medical Society at its June meeting; the participants were Drs. William C. Blake, Tampa; Spencer A. Folsom, Orlando; and Arthur H. Weiland, Coral Gables. The Leon-Gadsden-Liberty-Wakulla-Jefferson County Medical Society was addressed at Chattahoochee, recently, by Drs. Julius C. Davis, Quincy, on intestinal obstruction; James G. Lyerly, Jacksonville, acute craniocerebral injuries; Henry E. Palmer, Tallahassee, venereal diseases; and William D. Rogers, Jr., Chattahoochee, amebiasis. Dr. William C. Blake, Tampa, was elected president of the Florida Tuberculosis Association at its recent annual meeting.

GEORGIA

Chattahoochee Valley Meeting—The thirty-seventh annual meeting of the Chattahoochee Valley Medical Association will be held at Radium Springs, Albany, July 13-14. Dr. Julian Deryl Hart, professor of surgery, Duke University School of Medicine, Durham, N. C., will be the guest speaker, and Dr. Charles W. Roberts, Atlanta, will deliver the W. J. Love Memorial Lecture.

Personal—Dr. Glenn J. Bridges, Atlanta, has been appointed health officer of Jenkins County, succeeding Dr. Hugh B. Senn, Millen, resigned. Dr. Thomas B. Phinizy, Augusta, who has been acting commissioner of public health of Richmond County for the past year, has been appointed commissioner, effective July 15, when he will have completed five years as health officer in compliance with the state law.

ILLINOIS

Hospital News—A new four story wing to the Moline City Hospital, costing about \$256,000, was dedicated May 10. The new addition provides four operating rooms, two delivery rooms and accommodations for forty patients, giving the institution a total capacity of 170 beds.

Personal—Dr and Mrs Thomas A McTaggart, Pawnee, observed their fiftieth wedding anniversary, June 22.—Dr Julius B Stokes, assistant medical director of the Ottawa Tuberculosis Sanatorium, Ottawa, has been appointed medical superintendent of the Livingston County Tuberculosis Sanatorium, succeeding Dr Donald W Tripodi, Pontiac, resigned.

Clinic for Physically Handicapped Children—The newly created state division for physically handicapped children, state department of public welfare, held its first clinic in Shelbyville, June 25. Of seventy children of Shelby and adjacent counties who were examined, 60 per cent were under 10 years of age and about 80 per cent of them have been attending school despite severe handicaps, resulting from infantile paralysis, spastic paralysis and congenital deformities, among other conditions. No tuberculosis was found. Children in need of hospital care will be assigned to the Macon County Hospital, Decatur, and to St John's Sanitarium, Riverton, it was stated. Other clinics are planned as a part of the department's program, which is financed by a state appropriation of \$120,000 and a similar one from the federal government.

Chicago

Hospital News—The name of the Chicago Fresh Air Hospital has been changed to the Birchwood Park Sanitarium. The policy of the hospital has also been changed to permit physicians in private practice to send their patients to the hospital for personal treatment. Founded in 1909 as a tuberculosis hospital, the sanatorium has gradually changed during the past few years and now takes patients suffering from nervous disorders, heart disease and mild mental disease, aged and infirm persons requiring nursing care or rest, and diet cases. The name was changed to avoid confusion between the present policy and its original purpose.

Polish Meeting at State Hospital—The Chicago State Hospital was host to the Polish Medical Society of Chicago, June 16. Dr Edward F Dombrowski, managing officer of the hospital, gave the address of welcome and the following staff members presented papers:

- Dr Milton M Scheffler Malignant Endocarditis
- Dr Jacob V Edlin The Value of Vitamin B in Korsakow's Syndrome for Polyneuritis
- Dr Ola A Kibler The Follow Up Treatment in Cases of Syphilitic Meningo-Encephalitis Ten Years After Malaria Has Been Induced
- Dr Hyman H Goldstein Induced Hyperinsulinism

Dr Dombrowski also reported on the treatment of schizophrenia by insulin shock and the symptomatology of induced hyperinsulinism.

Dr Reed Honored—Dr Charles B Reed was guest of honor at a dinner at the Union League Club, June 23, given by the staff of Wesley Memorial Hospital and other friends to celebrate his completion of fifty years in the practice of medicine. Dr Philip H Kreuscher presided. Speakers at the dinner, at which a testimonial volume was presented to Dr Reed, included Dr Irving S Cutter, dean, Northwestern University Medical School, Mr F J Thielbar, president of the board of trustees, Wesley Hospital, Dr Robert B Blue, chief of staff at the hospital, Paul Fesler, superintendent, Rev John De Lacy and Dr Charles E Humiston Chicago, Dr Frederick G Novy, Ann Arbor Mich, and Dr Charles A Armstrong, Prairie du Chien Wis, a classmate of Dr Reed. Other classmates attended Drs Frederick E Vance, Eddyville, Iowa, Myrwood T Dixon, Columbus, Ohio, William H Cantwell, Shawano, and Henry G Ohls, Chicago. Dr Reed, who is associate professor of obstetrics at Northwestern, served as president of the Chicago Medical Society, 1929-1930, and as president of the Illinois State Medical Society, 1935-1936. He graduated from Rush Medical College in 1887.

INDIANA

Meeting of Laboratory Technicians—The Indiana Society of Clinical Laboratory Technicians held its annual meeting in Indianapolis, June 18-19. The speakers included Dr Clyde G Culbertson, on hematology, Rolla Neil Harger, Ph D, chemistry, and Dr Gerald F Kempf, bacteriology. At the annual banquet, Saturday evening, Dr Louis H Segar was the principal speaker.

Society News—The Grant County Medical Society was addressed at Marion, May 27, by Dr Bert E Ellis, Indianapolis, on "Treatment of Diseases and Fractures of the Nasal Accessory Sinuses".—At a meeting of the Hendricks County

Medical Society in Danville, May 27, Dr Bennett Kraft, Indianapolis, spoke on the allergic diseases.—A round table discussion on the treatment of syphilis was presented before the Orange County Medical Society in Orleans, June 2.—Dr Robert J Hawkins, Chicago, gave a paper before the Porter County Medical Society in Valparaiso, May 25, entitled "Eclampsia, Placenta Praevia, Disproportions".—Dr Eshe Asbury, Cincinnati, addressed the Dearborn Ohio County Medical Society in Lawrenceburg, June 3, on "Intracapsular Fractures of Femur".—The Wayne-Union Counties Medical Society was addressed in Liberty, June 10, by Dr Clyde Clark, son Payne, Dayton, Ohio, on "Physical Defects in School Children".—Dr Edward C Rosenow, Rochester, Minn., addressed the Muncie Academy of Medicine, May 11, on "Focal Infection and Elective Localization, A Review and Newer Findings".

KANSAS

Personal—Dr Claud E Hardin, Oswego, has been appointed health officer of Labette County, succeeding Dr Onnie E Stevenson, who has resigned to become assistant superintendent of the state hospital at Parsons. Dr Stevenson had been health officer twelve years.—Dr Leo V Turgeon, Wilson, has been appointed a member of the state board of administration.—Dr Clyde W Miller has been appointed superintendent of the Sedgwick County Hospital at Wichita.

Society News—At a meeting of the Clay County Medical Society in Clay Center, May 19, Dr Lloyd O E Pecken schneider, Halstead, discussed pathologic chest conditions.—The Ford County Medical Society was addressed, May 14, by Drs Christian A Hellwig and Vern L Pauley, Wichita, on "Colloid or Toxic Gorter" and "Classification of Gorter" respectively.—At a meeting of the Meade-Seward County Medical Society in Liberal, May 7, Drs Jefferson R Lemmon and James W Hendrick, both of Amarillo, Texas, discussed "Pylorospasm" and "Pelvic Pains" respectively.—Dr Norman Reider Topeka, addressed the Pratt County Medical Society in Pratt May 28, on "Brain Tumor" and Dr Warren F Bernstorff, Winfield, "Value and Indications for Sedimentation Test".—The Wyandotte County Medical Society was addressed in Kansas City, May 18, by Drs Ward W Summer ville on "Bronchogenic Carcinoma" and Galen M Tice, "Radiology of Bronchogenic Carcinoma".

LOUISIANA

Personal—Dr Benjamin Freedman, New Orleans, has been appointed in charge of the Washington Parish Health Unit. Dr Virginia E Webb, who was temporarily in charge of the unit, has returned to her work in the maternal and child health unit in New Orleans, it is reported.

New Tuberculosis Hospital—The dedication of the new G B Cooley Sanatorium at White's Ferry, near Monroe, took place in June. The WPA supplied most of the funds for the sanatorium, which cost \$121,000. One unit will care for twenty two white patients, while a second unit will accommodate twenty-six Negro patients. The sanatorium occupies a 26 acre site bought with Christmas seal funds and is named after Mr G B Cooley, president of the Ouachita Tuberculosis and Public Health Association.

MARYLAND

Dr Gregersen Goes to Columbia—Magnus I Gregersen, Ph D, professor of physiology, University of Maryland School of Medicine, Baltimore, has been appointed professor and head of the department of physiology at Columbia University College of Physicians and Surgeons, New York, succeeding Dr Horatio B Williams, who resigned a year ago. Walter S Root, Ph D, associate professor of physiology at Maryland, will also join the Columbia faculty as associate professor of physiology. In 1930 Dr Gregersen received his degree of doctor of philosophy at Harvard, where he taught for several years in the department of physiology.

Dr Ford Retires as Professor of Bacteriology—The retirement of Dr William Webber Ford as professor of bacteriology in Johns Hopkins University School of Hygiene and Public Health, Baltimore, is announced in *Science*. As a memento of the occasion a collection of rare or unusual books in bacteriology and mycology will be presented to him by former students and associates. Dr Ford was born in Norwalk, Ohio, in 1871. Graduating from Johns Hopkins University School of Medicine in 1898, he joined its faculty in 1903 and served subsequently as instructor in bacteriology, associate in bacteriology and associate professor of hygiene and bacteriology and lecturer in legal medicine. He has held the professorship at the School of Hygiene and Public Health since 1917.

MASSACHUSETTS

The Five Year Study of Pneumonia—A final report of the five year survey of pneumonia in Massachusetts has been completed. The study was financed by the Commonwealth Fund and carried out under the auspices of the Massachusetts Department of Public Health. Epidemiologic studies revealed for the first time that of all the types only type I and type II have special epidemiologic significance. Type I was found twenty times as prevalent in immediate family contacts of type I cases as in the population at large and type II ten times as prevalent. Investigation of cases showed that about 20 per cent of family contacts with type I or II cases became carriers of such types, while only about 2 per cent of hospital contacts became carriers. It was found that some factor in addition to contact alone was needed to determine the transfer of type I or II pneumococci from patients to contacts and this factor appeared to be the presence in such contacts of upper respiratory infections such as the common cold. A study of the incidence of all thirty-two types of pneumococci in the specimens sent for examination from patients with respiratory disease showed that, in nearly 10,000 such specimens examined, types I, III, VIII, II, V and VII, in this order, were the commonest and made up 67 per cent of all specimens containing pneumococci which could be typed. Data were gathered on the case fatality rates by types of 338 cases of lobar pneumonia cared for at home and of 367 others treated in hospitals. In none of these 705 cases was specific serum or vaccine administered. Records of 956 cases of lobar pneumonia treated with type I and II antiserum were obtained and analyzed. Of 504 type I cases treated within the first four days of illness only fifty-six, or 11.1 per cent, were fatal. Of 136 type II cases also treated early, thirty-seven, or 27.2 per cent, were fatal. It was estimated that the lives of eighty-nine patients were saved, proving that the early use of serum brought about a considerable reduction in the fatality rate of the treated cases. The report recommended the continuation of typing at the state bacteriologic laboratory for the thirty-two known types, permitting the month by month follow up of the various types of pneumococci in a large group of pneumonias and other respiratory infections. This is important in view of the fact that during the study types V, VII and VIII were the three commonest higher types found, and evidence is accumulating that specific serum is of value for the treatment of pneumonia caused by any one of these types. Of the \$172,000 allowed by the Commonwealth Fund to finance the study, \$143,107.39 was expended. For the first four years the study functioned through "collaborator areas." Thirty trained technicians in twenty-eight hospitals did the typing and seventy-eight physicians collaborated. In 1935 the system was reorganized to distribute serum to all physicians of the state who wished to use it. When the survey ended, sixty-six laboratories scattered throughout the state were prepared to carry out pneumococcus typing. During the study the Krumwiede, Sabin, tube agglutination, precipitin, urine, Rosenthal and Sternberg and Neufeld methods of typing were used experimentally, but subsequent results led to the decision that the Neufeld be adopted as a routine procedure and that in the future it would no longer be necessary to check the results of a Neufeld typing by other procedures when the results were positive. The results of the study represent the combined efforts of nearly 400 Massachusetts physicians located in ninety-eight towns, who treated 213 patients in their homes and 742 patients in eighty hospitals throughout the state. In one case, it was not stated where the patient was treated. The educational aspect of the program included the distribution of literature, graduate courses, lectures for local and national societies, and meetings on pneumonia in areas chosen for intensive work. Dr Roderick Heffron was field director of the survey, in which Dr Elliott S. Robinson, director of the antitoxin and vaccine laboratory of the state department of health, cooperated in the study, which aimed to evaluate serum under conditions of general practice and to develop plans for its distribution.

MINNESOTA

Dr Balfour Named Director of Mayo Foundation—Dr Donald C. Balfour, associate director, Mayo Foundation, Rochester, has been appointed director, effective July 1, to succeed Dr Louis B. Wilson, who has become director emeritus. Dr Balfour received the degree of bachelor of medicine at the University of Toronto Faculty of Medicine in 1906 and that of doctor of medicine in 1914. He has been practicing in Rochester since 1907. He is professor of surgery at the Graduate School, University of Minnesota, and in 1935 was president of the American College of Surgeons.

MISSOURI

New Executive Offices—Executive offices of the Jackson County Medical Society have been opened in rooms 623-628 in the Shukert Building, 1115 Grand Avenue, Kansas City. Floyd K. Helsby was recently appointed executive secretary of the society, with Winona McGovern as his assistant.

MONTANA

Dinner in Honor of Guest Speaker—The Silver Bow Medical Society gave a dinner in honor of Dr Frank S. Rossiter, Swissvale, Pa., May 20. Later Dr Rossiter addressed the society on the effects of carbon monoxide on human beings. Dr Samuel E. Schwartz, Butte, president of the society, presided at the dinner.

NEBRASKA

State Medical Election—Dr Homer Davis, Genoa, was chosen president-elect of the Nebraska State Medical Association at the annual meeting in Omaha, May 13, and Dr Roy W. Fouts, Omaha, was installed as president. Drs William E. Shook, Shubert, and George E. Charlton, Norfolk, were elected vice presidents and Dr Roy B. Adams, Lincoln, continues as secretary. The 1938 session will be held at Lincoln.

NEW JERSEY

Conference on Venereal Disease—A statewide conference on control of venereal disease was held in New Brunswick, May 18. At a noon meeting Drs Jesse Lynn Mahaffey, state director of health, Trenton, and Raymond A. Vonderlehr of the U. S. Public Health Service, Washington, D. C., made addresses. In the afternoon there were group discussions of various problems and demonstrations showing methods of handling venereal disease patients. At an evening session Charles-Edward A. Winslow, Dr. P. H., New Haven, Conn., spoke on "The Romance of Syphilis" and Charles Walter Clarke, director of the social hygiene division of the New York City Department of Health, on "Our Immediate Objectives."

NEW MEXICO

Personal—Dr Julian O. Long, formerly health officer of the eighth district, has been placed in charge of the third district, with headquarters in Albuquerque. Dr John W. Elder has been acting health officer while Dr Long completed a course in public health work at Johns Hopkins University.

NEW YORK

Tuberculosis Hospital Superintendent Appointed—Dr John K. Deegan, Albany, assistant superintendent for several months at the new Hermann M. Biggs Memorial Hospital, Ithaca, has been provisionally appointed superintendent. The hospital which was opened Oct. 1, 1936, is one of three state sanatoriums for tuberculosis. Dr Deegan, a graduate of Albany Medical College in 1927, has been on the staff of the division of tuberculosis, state department of health, since 1933. Prior to his association with the department he served on the staffs of various sanatoriums for tuberculosis in New York and Connecticut.

New York City

Society News—A symposium on pituitary basophilism was presented at a meeting of the New York Endocrinological Society, May 26, by Drs. Bernard S. Oppenheimer, Solomon Silver, Irving H. Pardee and Aaron S. Blumgarten.—Drs. Collier F. Martin and Walter Estell Lee, Philadelphia, addressed the Medical Society of the County of Kings, May 18, on "Lymphopathia Venerea."

Consultants on Cancer Research Appointed—Columbia University has recently appointed a "Consulting Board in Cancer Research" with the following members:

Edmund B. Wilson, LL.D., Da Costa professor emeritus of zoology, Columbia.
Thomas Hunt Morgan, Sc.D., chairman of the division of biology, William G. Kerckhoff laboratories of the Biological Sciences, California Institute of Technology, Pasadena, Calif.
Gary N. Calkins, Sc.D., professor of protozoology, Columbia.
Henry C. Sherman, Sc.D., Mitchell professor of chemistry, Columbia.
Marston T. Bogert, Sc.D., professor of organic chemistry, Columbia.
Paul M. Giesy, Ph.D., associate professor of chemistry, Newark College of Engineering, Newark, N. J.
Ernest O. Lawrence, Ph.D., professor of physics, University of California, Berkeley.
Bergen Davis, Sc.D., professor of physics, Columbia.
Dr. Eugene H. Pool, clinical professor of surgery, Columbia.
Dr. William J. Mayo, Rochester, Minn.
Dr. George H. Semken, consulting surgeon, Knickerbocker Hospital, New York.
George B. Pegram, Sc.D., professor of physics and dean of the faculties of political science, philosophy and pure science, Columbia.

NORTH CAROLINA

Personal—Dr Warren Dallas Carter, Wilmington, has been appointed health officer of Burke and Caldwell counties to supervise units recently established in the two counties—Dr Wyman P Starling, Clinton, has resigned as health officer of Sampson County to enter private practice—Dr Paul A Yoder, superintendent of the Forsyth County Sanatorium, Winston-Salem, was elected president of the North Carolina State Tuberculosis Association at its recent annual meeting in Southern Pines

PENNSYLVANIA

Society News—Dr Ralph L Hill, Wernersville, addressed the Berks County Medical Society, Reading, June 15, on "Psychiatric Problems of Interest to the General Practitioner"—Dr Joseph S Baird, Pittsburgh, recently addressed the Fayette County Medical Society, Uniontown, on "Treatment of Contagious Diseases in General Practice"

Pittsburgh

Society News—Dr Fred L Adair, Chicago, addressed the Pittsburgh Obstetrical and Gynecological Society, June 4, on "Uterine Prolapse and Colpocleisis" and conducted a dry clinic on intracranial fetal trauma

Medical Bureau Not Sponsored by Medical Society—In a news item in THE JOURNAL, June 26, page 2232, appeared the statement "The Medical Bureau of Pittsburgh, sponsored by the Allegheny County Medical Society and the Odontological Society of Western Pennsylvania, opened June 1" According to the secretary of the county medical society, the bureau is not sponsored by that organization

RHODE ISLAND

State Medical Meeting and Election—Dr Walter C Rocheleau, Woonsocket, was elected president of the Rhode Island Medical Society at the annual session in Providence June 3-4 Drs Edward S Brackett, Providence, and Charles H Holt, Pawtucket, were elected vice presidents The mornings were devoted to clinics at the Butler, Memorial, St Joseph's, Miriam and Rhode Island hospitals, afternoon and evening sessions were held at the Rhode Island Medical Library Speakers included

Dr John F Erdmann New York Surgical Curiosities and Rarities
Dr Rosco G Leland Chicago director Bureau of Medical Economics American Medical Association Is Medicine to Be Socialized?
Dr Dana W Atchley New York Observations on Mechanisms Producing Shock
Dr Charles W McClure Boston Affections of the Colon
Dr Gilbert Horrax Boston Diagnosis and Treatment of Trigeminal Neuralgia and Meniere's Disease
Dr Herman A Lawson Providence Practical Aspects of the Diagnosis and Treatment of Pernicious Anemia
Dr Jesse P Eddy, III Providence Experiences with Blood Transfusion at the Memorial Hospital

Drs Frank H Lahey and Lewis M Hurxthal, Boston, John F Kenney, Pawtucket, Frederic V Hussey, Guy W Wells, Isaac Gerber and Cecil C Dustin, Providence, participated in a round table discussion on disorders of the thyroid

SOUTH CAROLINA

Promotions at Medical College—At the commencement of the Medical College of the State of South Carolina, Charleston, in June, the following promotions in the faculty were announced

Drs John F Townsend and Josiah E Smith to be professors of ophthalmology, otology, rhinology and laryngology
Dr Robert Lane McCrady associate professor of gynecology and obstetrics
Dr Henry William de Saussure associate professor of obstetrics
Drs William Atmar Smith Joseph Henry Cannon John Julius La Roche Jr and Olin B Chamberlain associate professors of medicine
Dr Thomas Hutson Martin assistant professor of surgery
Dr Pierre Gautier Jenkins assistant professor of ophthalmology, otology, rhinology and laryngology

TENNESSEE

Society News—At a meeting of the Dyer, Lake and Crockett Counties Medical Society at Reelfoot Lake, June 2, the speakers were Drs Rudolph H Kampmeier, Nashville, on "Chronic Nontuberculous Pulmonary Disease", William David Stravhorn Jr, Nashville, "Management of Cardiac Patients", Peter Whitman Rowland Jr, Memphis, "Diagnosis and Treatment of Rheumatoid Arthritis", and James B McElroy, Memphis, "Diseases of the Kidney"—Dr John M Stockman, Knoxville, addressed the Knox County Medical Society, Knoxville, June 8, on "Injection Treatment of Hemorrhoids"—Among speakers before the Hardin, Lawrence, Lewis, Perry and Wayne Counties Medical Society, Savannah, May 25 were Drs Henry B Gotten, Memphis, on protamine insulin,

and Emmett R Hall, Memphis, treatment of syphilis—Dr Mack I Shanholtz, Bristol, Va, and Thomas B Yancey, Kingsport, addressed the Sullivan-Johnson Counties Medical Society, Kingsport, June 2, on congenital syphilis and bacillary dysentery, respectively—Dr Wallace L Poole addressed the Washington County Medical Society, Johnson City, on "Use of Antipneumococcic Serum"

VIRGINIA

Faculty Changes at University—Dr Claude C Coleman, professor of neurologic surgery at the Medical College of Virginia, Richmond, has been appointed clinical professor of neurologic surgery at the University of Virginia Medical Department, Charlottesville, and Dr William Gayle Crutchfield, assistant professor of neurologic surgery at the Richmond college, associate clinical professor of neurologic surgery at the university They will continue on the faculty at Richmond, according to a newspaper report Dr John Moyer Meredith, resident in surgery at the Medical College of Virginia, Hospital Division, has been made assistant clinical professor of neurologic surgery, and Dr Cuthbert Tunstall has been promoted to be assistant professor of diseases of the ear, nose and throat at the university

WASHINGTON

Personal—Dr John H O'Shea, Spokane, received the honorary degree of doctor of laws from Gonzaga University, Spokane, recently—Dr Alfred E Eyres, Walla Walla, has been appointed health officer for the city and county of Walla Walla

Seattle Paper Prints Medical Supplement—The Seattle Times published an eight page medical supplement May 23 in tribute "to the doctor and medical science" The project was sponsored by the Public Health League of Washington with the approval of the Washington State Medical Association and the King County Medical Society The supplement contains information about the county and state societies and Seattle hospitals, a sketch of medical history in the Northwest, reviews of health conditions in the city and state and numerous bits of health advice

WISCONSIN

New Health Officials Appointed—Dr Milton Trautmann, Prairie du Sac, has been appointed to take charge of a program for control of venereal disease to be carried on by the state board of health Dr Trautmann was designated some months ago and has spent the intervening period in a special course of study at Johns Hopkins University Dr Paul A Brehm, Milwaukee, has been placed in charge of an industrial hygiene program initiated under the terms of the social security act

Society News—At the final meeting for the season of the Medical Society of Milwaukee County, the guest speaker was Dr Dwight L Wilbur, Rochester, Minn, on "Recognition and Treatment of Vitamin Deficiency States", and Dr Hobart K B Allebach, Milwaukee, discussed "Urinalysis as a Diagnostic Aid" The Milwaukee Professional Men's Orchestra presented a program—Dr Harry E Kasten, Beloit, was elected president of the Wisconsin Urological Society at the annual meeting recently in Kenosha—Dr Sara G Geiger, Milwaukee, addressed the Milwaukee Neuro Psychiatric Society, May 27, on "The Treatment of Conduct Problems in Penal Institutions"

GENERAL

Society News—Dr William D Donohoe, Los Angeles, was elected president of the Pacific Coast Oto-Ophthalmological Society at its twenty-fifth annual convention in Salt Lake City, May 25 Drs Donald H O'Rourke, Denver, and Morton J Keys, Victoria, B C, were chosen vice presidents and Dr Clifford Allen Dickey, San Francisco, secretary Next year's meeting will be in Victoria

Officers of Specialty Advisory Board—At the annual meeting of the Advisory Board for Medical Specialties in Atlantic City, Dr Willard C Rappleye, New York, was elected president, Dr William P Wherry, Omaha, vice president and Dr Paul Titus, Pittsburgh, secretary Dr Louis B Wilson, Rochester, Minn, retiring president, was made a member emeritus Drs Walter B Lancaster, Boston, and Robin C Buerki, Madison, Wis, were made members of the executive committee

Research in Child Neurology—Dr Bernard Sachs, director of Child Neurology Research, an organization established by the Friedsam Foundation in 1936 to develop research in child neurology and allied fields, has presented the first annual

report to the officers. Twenty-two grants were made in the first year in three general groups: general diseases of the nervous system, with special reference to their development in early life, early neuroses and psychoses, and a special group concerned with social, personality and home problems. Names of the recipients were not announced. Among the subjects under investigation are epilepsy and convulsions of children, pyknopsy, electrophysiology of brain activity, encephalitis and hydrocephalus, relation of artificial fever and convulsions tissue permeability as a factor in convulsive states, brain tumors of childhood, mechanism of choked disk and its relation to optic neuritis, surgical procedures on the bones, muscles and peripheral nerves in spastic paralysis, mental changes following birth injuries, sex awareness and sex attitudes in children, maladjustments in normal school children arising from inability to learn to read by present educational methods, lipoids in multiple sclerosis, nervous regulation of growth and resistance of tissues to avitaminosis. It is planned to publish all work done under the auspices of the organization from year to year in special volumes.

Requests and Donations—The following bequests and donations have recently been announced:

Beth Israel Hospital New York \$5 000 by the will of David Epstein
Philadelphia Cancer Hospital \$1 000 from the estate of Mrs. Mary C. Vaughan

Methodist Episcopal Hospital Philadelphia \$25 000 by the will of Miss Sarah E. Simpson

Maternity Hospital Philadelphia \$15 000 and University Hospital Philadelphia \$5 000 to provide a prize each year for the nurse graduating at the head of her class by the will of Mrs. Letitia White widow of Dr. J. William White

Bloomsburg Hospital Bloomsburg Pa. \$10 000 and ultimately the bulk of a \$150 000 estate left by Dr. J. J. Brown and his sisters

Shriners Hospital for Crippled Children and Children's Hospital Philadelphia \$1 000 each Bryn Mawr Hospital Bryn Mawr Pa. and Chester Hospital Chester Pa. \$2 500 each and Crozer Hospital Chester \$1 000 by the will of the late Henry W. Roth

New York Post Graduate Medical School and Hospital one half the estate of the late Mrs. Mathilda Watson valued at more than \$100 000

Hospital for Joint Diseases New York \$10 000 by the will of the late Henry Dazian

The First Rocky Mountain Conference—A military hour to close each afternoon's program will be a feature of the first Rocky Mountain Medical Conference at Denver July 19-21. Addresses on "Defense Against Chemical Warfare," "Parasitology" and "Modern Trends in Aviation Medicine" will be presented by medical officers assigned to the conference from the eighth corps area, and reserve officers will receive credit for attendance. Speakers at the conference will include Dr. William C. Woodward, Director, Bureau of Legal Medicine and Legislation, American Medical Association, Chicago; on "Current and Prospective National Legislation Affecting Physicians" and Dr. Eldridge L. Eliason, Philadelphia. "The Surgical Significance of Indigestion" Dr. Thomas Parran, surgeon general U. S. Public Health Service will address a public meeting in the Denver Municipal Auditorium July 20, on "The Campaign Against Syphilis." He will also address the conference. Others on the program include:

Dr. Roscoe R. Spencer, U. S. Public Health Service, Washington, D. C.

Dr. Walter C. Alvarez, Rochester, Minn.

Dr. Walter E. Dandy, Baltimore

Drs. Julius H. Hess, Herman L. Kretschmer and Walter L. Palmer, Chicago

Dr. Hayes E. Martin, New York

Dr. William B. Carroll, Dallas

Dr. Leo G. Rigler, Minneapolis

Dr. Charles C. Dennis, Kansas City, Mo.

Dr. Gabriel Tucker, Philadelphia

Dr. Sterling Bunnell, San Francisco

Dr. Andrew J. Browning, Portland, Ore.

Dr. Earl C. Sage, Omaha

The conference is sponsored by the state medical societies of Colorado, New Mexico, Utah and Wyoming. There will be a registration fee of \$3.

The Golf Tournament at Atlantic City—One hundred and sixty-seven medical golfers from all parts of the United States and from the Hawaiian Islands played the beautiful Seaview Country Club course in Atlantic City on the occasion of the twenty-third annual tournament of the American Medical Golfing Association, Monday, June 7. Most of the entrants played thirty-six holes, with a swim in the club's salt water pool between the first and second rounds. Ideal weather was scored, and the record was broken by the lowest championship scores. The 129 trophies and prizes were awarded after the golfers' dinner at Seaview, presided over by Dr. William Albert Cook, Tulsa, Okla., president of the A. M. G. A. Dr. Walt P. Conaway, Atlantic City, was chairman of the local golf committee in charge of arrangements.

The championship was won by Dr. William J. Van Wie, Mount Vernon, N. Y., who turned in a 75-73-148 for the thirty-six holes. He received the famous Will Walter Trophy,

named in honor of the dean and organizer of the A. M. G. A., who now resides in Charlottesville, Va.

The Handicap Championship was won by Dr. Paul H. Shiffer, Stroudsburg, Pa., who bagged the Detroit Trophy, presented by the Detroit hosts in 1916. The Eighteen Hole Championship went to Dr. Clarence E. Moore, Harrisburg, Pa., with a sterling 73 for the first eighteen holes played. The Eighteen Hole Handicap Championship was awarded to Dr. W. Albert Cook, who won the Ben Thomas Trophy.

The Maturity Event, limited to Fellows over 60 years of age for the best net score on the first eighteen holes, was tied by Drs. Harry M. Schuffell, Canton, Ohio, and Jesse B. Sampsell, Van Wert, Ohio. On the toss, Dr. Schuffell won the Minneapolis Trophy. Dr. Sampsell was presented with the Hotel Dennis prize, the third prize went to Dr. George H. Fellman, Milwaukee, the fourth prize to Dr. Joseph F. Hawkins, Providence, R. I.

Dr. Walter D. Shelden of Rochester, Minn., president and also champion of the A. M. G. A. in 1928, won the Old Guard Championship awarded to past presidents, and received the Wendell Phillips Trophy. Dr. Charlton Wallace, New York, president in 1922, won second prize, and Dr. Edwin G. Zabriskie, New York, president in 1931, took third prize.

The Championship Flight low gross was won by Dr. Edmund B. Sullivan, Mount Vernon, N. Y., who secured the St. Louis Trophy. Other winners were Drs. Farrell T. Gallagher, Lakewood, Ohio, James Marek, Cleveland, and John A. Krosnoff, Bentleyville, Pa. The first net prize in this flight went to Dr. William R. Brewer, Altoona, Pa., who won the President's Trophy, a sterling silver pitcher presented by Dr. W. Albert Cook. Other winners were Drs. John H. Harris, New York, Stanley Q. West, Philadelphia, Clarence W. Hullinger, Springfield, Ohio, and William C. Warren, Atlanta, Ga.

The First Flight gross winners were Drs. James R. Chandler, Daytona Beach, Fla., David H. Houston, Seattle, Carl H. McCaskey, Indianapolis, and Tobias C. Shookers, Lancaster, Pa. First prize among the nets was won by Dr. Homer R. Mather, Latrobe, Pa. Other prize winners were Drs. Thomas A. Kyner, Kansas City, Harry V. Hubbard, Plainfield, N. J., Alonzo C. Smith, Wooster, Ohio, and Herman S. Zeve, Youngstown, Ohio.

The Second Flight gross winners were Drs. John F. Rogers, Poughkeepsie, N. Y., Waltman Walters, Rochester, Minn., Sobisca S. Hall, Clarksburg, W. Va., and George L. Bauman, Cleveland. Net prizes went to Drs. Joseph Halton, Sarasota, Fla., James C. Joyner, New York, Karl R. Ruddell, Indianapolis, and Alvin Hulnick, Staten Island, N. Y.

The Third Flight gross winners were Drs. Frank H. Lahcy, Boston, Nathaniel B. Stanton, Plainfield, N. J., Hugh A. Gestrung, Kansas City, and R. Donald Beck, New York. Net winners in this flight were Drs. John R. Fowler, Spencer, Mass., William McLean, New York, Joseph J. Labov, Elizabeth, N. J., Jacob M. Sutherland, Detroit, and Rial R. Oglevie, Kansas City.

Fourth Flight gross winners were Drs. Wilbur H. Haines, Philadelphia, Lyman W. Crossman, New York, Park A. Deckard, Harrisburg, Pa., and Walter J. Wilson, Detroit. Winners of the net prizes were Drs. Robert H. Ivy, Philadelphia, Lloyd W. Johnson, Pittsburgh, James G. Boyes, Plainfield, N. J., James N. O'Brien, Harrisburg, Pa., and Joseph E. Roberts Jr., Haddonfield, N. J.

Fifth Flight (net only) winners were Drs. George H. Fellman, Milwaukee, Sylvester E. Lentz, Leighton, Pa., Roy L. Langdon, Philadelphia, Bonnelle W. Rhamy, Fort Wayne, Ind., and Francis P. McCarthy, Boston.

The Blind Bogey, or Kickers' Handicap, was won by Dr. John C. Kenning of Detroit, who bagged the new Atlantic City Trophy, presented by the hosts of 1937—a sterling silver platter etched with the Atlantic City skyline. Winners of the other prizes were Drs. John S. Lewis Jr., Youngstown, Ohio, Edwin W. Grubb, Akron, Ohio, William C. Warren, Atlanta, John P. DeWitt, Canton, William R. Brewer, Altoona, Arch M. Paulson, Plainfield, N. J., John W. Shirer, Pittsburgh, Erastus S. Edgerton, Wichita, Kan., Byrl R. Kirklin, Rochester, Minn., Charles Falkowsky Jr., Scranton, Theodore M. Wille, Lakewood, Ohio, Lawrence O. Toomey, Bowling Green, Ky., Warren W. Quillian, Coral Gables, Fla., Joseph O. Collins, Waterbury, Conn., William P. Chalfant Jr., Ventnor, N. J., John L. Lattimore, Topeka, Kan., Frank M. Schrack, Pittsburgh, Louis B. Gloyne, Kansas City, Kan., Leonard G. Redding, Scranton, and Samuel D. Zuker, Toledo.

Dr. Walt P. Conaway of Atlantic City, who managed the tournaments of 1919, 1925 and 1935 in that city, was chosen by unanimous vote as president of the A. M. G. A. for the ensuing year. Dr. Erastus S. Edgerton, Wichita, was reelected first vice president, and Dr. George Washington Hall, Chicago,

was chosen second vice president Dr Cook of Tulsa, retiring president, was made a member of the board of directors The next meeting will be held in San Francisco at the time of the 1938 A M A annual session

CANADA

Dr Archibald Receives Bigelow Medal—Dr Edward W Archibald, professor of surgery and director of the department of surgery, McGill University Faculty of Medicine, Montreal, was presented with the Henry Jacob Bigelow Medal of the Boston Surgical Society, May 21, at the Boston Medical Library Dr William C Quinby, Boston, president of the society, made the presentation, and Dr Archibald spoke on "French Surgery in the First Half of the Nineteenth Century" Under the will of William Sturgis Bigelow, in memory of his father, a sum of money was presented to the society, "the income of which is to be used from time to time for the presentation of a gold medal to some outstanding surgeon for his work in the advancement of the science of surgery" Dr Archibald is 74 years of age He graduated at McGill in 1896

LATIN AMERICA

Law Requires Campaign Against Tuberculosis—A law was recently passed by the Colombian congress outlining an antituberculosis campaign and placing it under the direction of the National Department of Health, according to *Public Health Reports* The department is authorized, after a study of the problem, to provide antituberculosis vaccination To further the campaign, stamps will be issued and associations will be formed, and an appropriation of not less than 300,000 pesos is authorized annually for the next ten consecutive years Compulsory instruction in the prophylaxis of infectious diseases, especially tuberculosis, is to be required in the primary and secondary schools, and annual chest examinations of teachers in all schools and colleges is made compulsory, as well as of children where there is an official medical service

Government Services

Spotted Fever Vaccine

Spotted fever vaccine in sufficient quantities to vaccinate 1,387 persons has been supplied to the Rural Resettlement Administration by the Rocky Mountain Spotted Fever Laboratory, Hamilton, Mont, according to the *Health Officer* Vaccination is limited to persons living in zones having a high incidence of tick infestation in Montana, Oregon and Colorado

Health Education Activities

As a part of its studies in the evaluation of health department procedures, the division of public health methods of the U S Public Health Service plans to undertake studies of the health education activities of health departments, according to the *Health Officer* As a primary step, attention will be paid to the educational work of nurses and physicians in their contact with patients An analysis will be made of the informational content of the contacts and also the educational methods followed in instructing patients, it was stated

Entomologist Honored

Dr Leland Ossian Howard, former chief of the bureau of entomology, was honored, May 27, when entomologists of the U S Department of Agriculture and the Entomological Society of Washington and members of the Insecticide Society of Washington gathered to celebrate his eightieth birthday Dr Howard was made chief of the division of entomology, as it was then called, in 1894 He became assistant entomologist shortly after his graduation from Cornell University in 1877 In 1904 the division became a bureau of the Department of Agriculture, with Dr Howard as director until his retirement from active administration in 1927 He continued his association with it for the next four years Georgetown University conferred on him in 1896 the honorary degree of doctor of philosophy, and in 1911 George Washington University gave him an honorary degree of doctor of medicine He is honorary curator of the U S National Museum and an honorary member of the Medical Society of the District of Columbia He is a member of many scientific societies and has served as president of several Books he has written include "The House-Fly—Disease Carrier," published in 1911, and "The Insect Menace," published in 1931

New Regulations for Registration of Medical Students

The Register of Medical Students has been compiled from the forms of request for registration which students filled in at the various medical schools and has never been complete. The General Medical Council has therefore decided to request all the deans of medical schools to send copies of their students' register, from which the council's register will in future be compiled The council has also adopted new conditions of registration The intending student must be 18 years of age or within three months of that age He must have passed a recognized preliminary examination in general education and an additional examination or examinations recognized by the licensing bodies The minimum standard of general education is, as before, that of a university matriculation or entrance examination in the faculties of arts or pure science The additional examination or examinations include chemistry, physics and, for students who have learned their chemistry and physics at school, one or two subjects of general education at a standard higher than that of the recognized preliminary examination in general education Students may take biology either before or after they are registered The reason for this change in the regulations is that since 1923 English schools have been teaching physics and chemistry to boys who intended to take up medicine, and a pernicious tendency has developed of allowing boys to pass their test in general education at 16 and sometimes even before, and then setting them to study nothing but medical subjects for the rest of their time at school The new regulations are intended to combat this tendency

The Treatment of Tabes Dorsalis

At the Medico-Chirurgical Society of Edinburgh, Dr Robert Lees described the results of his treatment at the Royal Infirmary of 200 cases of tabes dorsalis in which a period of two years' administration of tryparsamide and a bismuth compound had been completed He referred to the differences of opinion at present between neurologists, ophthalmologists and syphilologists regarding the treatment of neurosyphilis He arranged his scheme of treatment in courses consisting of one attendance weekly for ten successive weeks and then an interval of one month before the next course The tryparsamide was given by intravenous injection of from 2 to 3 Gm and the bismuth compound by intramuscular injection of from 0.2 to 0.3 Gm. The tryparsamide practically never caused vasodilator phenomena, jaundice was infrequent and dermatitis rare. The risk of toxic amblyopia, provided due care was taken, he considered exaggerated In cases of optic atrophy the risk was considerable but the results appeared to justify the treatment.

The majority of the patients secured marked relief from the tabetic pains, 78 per cent were improved, 16 per cent remained stationary and 5 per cent were worse Ataxia was definitely improved in 65 per cent For this symptom the drug treatment was combined with massage, exercises and, in the advanced cases, reeducation in locomotion The treatment of the urinary symptoms was usually successful, especially in males For cystitis, catheterization, irrigation and instillation were used. The gastric crises became less frequent and less severe under the antisyphilitic treatment In the crises, injections of morphine and atropine were sometimes required, for the rectal crises, suppositories of atropine were used Arthropathies evinced considerable power of recovery under a combination of orthopedic and antisyphilitic treatment In early cases, if the affected joint is immobilized or protected from trauma for

some months the effusion may subside, the ligaments become more taut, the new bone and loose bodies largely disappear, and the joints return to almost normal function. In later cases the best that can be expected is ankylosis in good position. In advanced cases surgery may be necessary. Optic atrophy gave disappointing results, but they were equal to those recorded for other methods of treatment. For this condition the technic was modified. The patient was prepared by intensive and rapid saturation with iodides, and then bismuth was given in a form rapidly assimilated. The tryparsamide was given in moderate dosage. Rapid loss of vision or definite toxic symptoms, such as flashes of light, blurred vision and colored vision, were signals for stopping the drug. In those who showed no visual symptoms and in whom the atrophy progressed but slowly, active treatment was continued. Muscular atrophy was occasionally found. It responded well to treatment, complete recovery taking place if the diagnosis was made early. Juvenile tabes was associated with a high incidence of optic atrophy, but with none of the symptoms of adult tabes except urinary incontinence. The prognosis was not so good as in adults.

In the discussion, Prof. Edwin Bramwell said that nowadays pronounced cases of tabes were rarely seen because syphilis received such thorough treatment in the early stage. There was no evidence, as far as he knew, that any other drug than tryparsamide influenced the progressive course of optic atrophy.

Decline in Venereal Diseases

Venereal diseases are treated in this country at treatment centers maintained by the Ministry of Health. According to the latest annual report, published for 1935, the number of centers is 185, of which 119 are conducted at voluntary hospitals. After the war the number of cases of syphilis treated at the centers reached the high figures in 1919 and 1920 of 42,134 and 42,805 respectively. Then a continuous drop took place, in 1921 to 32,733, and in the following years to 25,762, 23,927 and 22,010. With the interruption of a slight rise (to 22,588) in 1925, the fall was subsequently continuous until 1935 when the number was only 19,335. The cases of soft chancre show a similar fall, from 2,442 in 1920 to 1,112 in 1935. The cases of gonorrhea have shown no such decrease, but a fluctuation. From 40,284 in 1920 they fell to 29,477 in 1922 and then increased to 45,001 in 1930, then falling to 41,332 in 1935. The effect of the war is shown by the fact that from its outbreak on Aug. 4, 1914, to its close on Nov. 11, 1918, the cases of syphilis treated in the British army (excluding dominion, colonial and Indian forces) were approximately 100,000. Between the close of the war and the completion of demobilization, the incidence of venereal diseases in the army greatly increased. The return of the infected men to their homes must have spread these diseases.

Outbreak of Typhoid Due to a Contaminated Stream

Excellent sanitary conditions have rendered typhoid, which was a common disease in the previous generation, very uncommon. An outbreak that occurred last year at the seaside resort of Bournemouth has been traced to an unusual source. When it was reported to the Ministry of Health, one of its medical officers, Dr. W. V. Shaw, sent to investigate, found that thirty cases had been notified in the last twenty-four hours. The patients were scattered and the only common factor was the consumption of raw milk from one distributor. Pasteurization was ordered and the outbreak at once stopped. No source of infection could be found among the personnel employed for distribution. So investigations were directed to the thirty-seven farms, scattered over a large part of Dorset, from which the milk was obtained. Two persons, the wife and son, aged 12, of one of the producers, were found to be suffering from typhoid, pointing to this milk as the source of the outbreak. The water supply was derived from a well 162 feet deep.

Repeated examination of the well water proved that it was liable to pollution. The condition of the nearby stream was investigated, and about half a mile from the farm a sewage effluent was found to be discharging into it from a house. Bacteriologic examination of the effluent for typhoid bacilli at first was negative but later they were found in large numbers. The occupants of the house were then examined and a typhoid carrier was found.

Freeing Cattle from Tuberculosis

A government scheme to increase the number of herds of cattle officially certified to be free from tuberculosis has been issued. It offers additional financial inducements to owners of herds to qualify for a certificate placing them on the Register of Attested Herds. If a herd of cattle has been tested and found not to contain more than 10 per cent of reactors, and these have been disposed of, the owner may apply to the Ministry of Agriculture for financial assistance toward the cost of further tests. This contribution will be at the maximum of 50 cents a head of the cattle tested plus \$5 a herd, but the contribution will not exceed the charge made by the veterinary surgeon carrying out the tests. When a herd fails to pass the test, the owner will have the opportunity of applying for three further official tests at the expense of the ministry. Herds accepted for these official tests will be known as supervised herds, and the owners will have to comply with rules regarding the disposal of reactors and disinfection of premises.

The Centenary of the State Registration of Births and Deaths

It is exactly 100 years since the state service for the registration of births, deaths and marriages was established in England. For vital statistics before 1837 there is only the imperfect substitute of ecclesiastical records. The government has had a silver medal struck to commemorate the centenary. The obverse bears the conjoined portraits of Queen Victoria and King George VI, the sovereigns reigning at the inception and centenary of the service. The reverse bears a device symbolic of the continuity of human life, perennially renewed through the stages of birth, marriage and death. The device is the Lampadephorian torch, the torch borne in the Lampadephoria, or relay races, which were a feature of the games of the ancient Greek city of Amphipolis. The traditional form of the torch was ascertained from its representation on coins in the British Museum.

Reduction of Atmospheric Pollution

Urbanization and industrialization have created a grave problem of atmospheric pollution in this country, with which a smoke abatement movement has tried to grapple. The twenty-second report on the investigation of atmospheric pollution has been issued by the Department of Scientific and Industrial Research and shows that on the whole there has been a definite reduction in the extent of the pollution of the atmosphere of Great Britain in the last twenty years. In the last two years there has been a small increase, which is accounted for by increased industrial activity. London showed a marked improvement between 1915 and 1922, but since then there has been an increase in the deposit of sulfates and a slight increase in the deposit of tar. One of the worst stations for tar deposits was Golden Lane, London, where the gage showed a deposit of 10.44 tons per square mile, an increase of 243 per cent on the general average for the last five years. The deposit of total solids compares unfavorably with last year. The greatest increase was found in London, where it amounted to 405 tons to the square mile, or 158 per cent of the general average. London has the highest average pollution by sulfur gases which accounts for the deterioration of building stone and possibly is injurious to health.

Tuberculin Reactions and the BCG Vaccine

Since the more widespread use of the BCG vaccine, often however not in accordance with the instructions of the Pasteur Institute as to periodic revaccination, there has been a tendency to abandon the tuberculin epidermal reaction in the diagnosis of tuberculous infection in children. At the April 13 meeting of the Academie de medecine Armand-Delille, Lestocquoy and Banu reported a study of 1,048 children, new-born or vaccinated at birth but seldom revaccinated. The ages varied from new-born infants to children 14 years of age, 119, or 119 per cent, of these had been given the BCG vaccine by mouth during the first week of life, with one exception, in which it had been given hypodermically. In nonhospitalized children, not a single positive reaction was observed in those who had been vaccinated. In their hospital service, the positive reactions varied from 10 to 17 in the case of vaccinated and from 10 to 15 per cent in the case of nonvaccinated groups. The intradermoreactions always were found negative in nurslings less than a year old who had been vaccinated at birth. The authors concluded that the epidermal and intradermal reactions conserved all their value for the diagnosis of a tuberculous infection, since the BCG vaccine, given in three doses in a week at birth, given by mouth, did not alone cause it to appear during the first year.

In the discussion, Guerin of the Pasteur Institute stated that some children did not react to tuberculin following vaccination by the oral route, or even following the intradermoreaction in doses progressively higher than those commonly employed. He considered the latter reaction a far more sensitive one. It must be admitted that in such cases the number of "bacillus vaccines" which had been absorbed had not been sufficient to provoke the follicular lesion which should have automatically given rise to the positive tuberculin reaction. In revaccinating with the BCG either by the epidermal or the intradermal route, in increasing the doses of the vaccine, it always happens that a positive reaction to tuberculin is observed. This reaction is slight and diffuse, and an experienced observer cannot mistake it for the positive reaction caused by the virulent bacillus, which is sharply cut, marked and lasting. Following vaccination by mouth, allergy will always be found toward the second or third month. Later it is rarely seen, hence the necessity of revaccinations. If allergy and premunition are considered as two related terms, which appears probable, an indication exists to repeat the vaccinal absorption and if necessary to increase the amount of vaccine to be absorbed. It is toward this eventuality that present trials are being directed.

A Paralytic Form of Infection in Chickens, Possible Relation to Acute Poliomyelitis

A bacteriologist of Romans, France, M. Cotte, reported his observations at the April 20 meeting of the Academie de medecine on a disease in chickens, which has been regarded for some time by veterinarians as a form of rheumatism. The symptoms are somnolence, anorexia and difficulty in remaining in the upright position, accompanied by claudication and a progressive atrophy, with cyanosis of the legs at times. In chicks as well as in adults, on the intestine, liver, peritoneum, pericardium and pleura, a veil-like whitish gray membrane of variable thickness can be seen. In the various joints of the legs and wings and on the inner aspect of the skull, similar discrete areas were noted. A gram-positive micrococcus was found in these membranes, and the same organism can be found in fertile eggs after four days of incubation, in freshly laid eggs and in the ovaries and oviducts. The alimentary origin of the infection was well established for two series of hatchings and appears probable for the others. According to certain

epidemiologic observations, the author raised the question whether this organism (*Micrococcus albus-gallinarum*), found in such infected chickens, could not be etiologically related to acute poliomyelitis in children.

Abuse of Free Medical Care in Parisian Public Hospitals

A bill has been submitted to the lower house of the French legislature which aims to correct the indiscriminate admission of patients who are able to pay for medical care to the many Parisian public hospitals and dispensaries. Paris lies in the department of the Seine, and all the institutions for indigents are under the control of the Assistance publique, whose director, although a physician, has been anxious to present a high number of admissions and correspondingly large receipts in the supposedly free hospitals and dispensaries. There are more than 35,000 beds at the disposal of the Assistance publique.

In the April 1937 Bulletin of the Syndicate of Physicians in the department of the Seine, the secretary, Dr. Barlerin, states that the Assistance publique, which receives hundreds of millions of francs for its budget annually from the city of Paris, ought not to attempt to become a commercial enterprise. As the result of the large subsidies received, of legacies, of the many new buildings that are being erected for it and, above all, of the fact that it pays no taxes, the administration of the public hospitals has innumerable advantages in competing with private hospitals, which are chiefly dependent on their receipts from patients and are obliged to pay relatively high taxes.

The proposed law aims to separate those who in the future will be refused admission to public hospitals from those who must be admitted as indigents. The latter will be given perpetual cards which entitle them to admission as indigents inscribed on the public relief lists. Cards will be given, after investigation, to persons who are temporarily unable to pay for hospital care. The latter class of cards would be given, following an inquiry into the individual case, by a committee in each hospital district. One half of the members of such a committee will be representatives of the Assistance publique, the other half members of the organized local medical profession and respective hospital staffs. Exceptions would be made in the second class of cards for emergency cases. The same form of admission will be used for public dispensaries. There have been many abuses of free treatment in the latter class of institutions, so that the medical profession in Paris has made innumerable protests against people who were well able to pay private physicians being treated, without any investigation of their financial resources, at public dispensaries.

Diabetic Gangrene and Tetanus

At the April 23 meeting of the Societe medicale des hopitaux an unusual complication in a case of diabetic gangrene was reported by Boulon, Uhry and Charousset. A farmer, aged 46, entered the hospital Dec. 26, 1936, on account of gangrene of the toes. A diagnosis of diabetes had been made ten years before. During the two years preceding admission, marked emaciation was noted and during the past year slight recurrent pains in the toes. Toward the end of November 1936 areas of gangrene had been noticed on several toes of both feet. He continued to walk, wearing shoes that were torn, thus permitting contact with the dirt of the country roads. Examination of the urine failed to reveal albumin, sugar or acetone, but the blood showed a definite hyperglycemia. The treatment included the administration of 40 units daily of insulin and a diet containing 68 Gm. of preformed carbohydrates. The toes were dressed with an antiseptic powder. About six weeks after the appearance of the gangrene, a slight trismus was noted. This increased in intensity, so that three days later it was very marked and accompanied by the typical signs of tetanus. Serotherapy was begun immediately. Sixty thousand units of tetanus antitoxin was given on the third day following

the onset of the tetanus symptoms and an injection of tetanus toxoid also was given on the same day. A total of 240,000 units of antitoxin was injected by the subcutaneous and intramuscular routes. A week after beginning the antitetanic treatment the symptoms of this complication had entirely disappeared. Only seven similar cases have been reported and in only two of these (those of Massabau and of Waltman Walters) were the tetanus bacilli found. Such a complication is rare, because contact between the gangrenous areas and dust containing the tetanus bacillus is uncommon. Death occurred in all previously published cases. The tetanus did not seem to have an unfavorable influence on the diabetic condition in the case reported by Boulin and his associates.

Record Book for Venereal Disease Patients

The ministry of public health has just issued an order creating the establishment of a personal record book to be given to every one suffering from a venereal disease. It will be recalled that every physician is now obliged to notify the health authorities when consulted by any person with venereal disease. The name of the patient will not be recorded in the new record book. Only a number will be given to designate the venereal disease patient. In this new book, physicians who have had occasion to treat a given case will record (1) the diagnosis and essential portions of the clinical history, (2) the various treatments that have been given and (3) instructions which the patient should follow. If the patient leaves the public health service in which the diagnosis and treatment were given, the record book can be given to the patient or forwarded to the physician he desires to consult next. The public health services will be obliged to keep duplicate records in order that a new personal book can be furnished, should the patient lose the original book.

Vitamin A Applications in Treatment of Burns

Reference was made in a recent letter to the use of vitamin A in the treatment of typhoid at Marseilles. The property of this vitamin to aid healing of wounds has been utilized by Professor Chevallier of Marseilles and two of his associates, Carcassone and Luccioni. Five patients who had burns of the second and third degree were treated following cleansing of the surfaces, alternately with a 1:4000 dilution of methylene blue and with vitamin A in cod liver oil. After application of these to the burns, the latter were at first left exposed to the air under frames covered by sterile sheets, then dressings saturated with these two solutions were applied every two days. In all five cases cicatrization took place very rapidly and the newly formed epidermis was very supple. The authors warmly recommend the use of vitamin A for burns.

New Director of Public Relief Administration

Dr. Mourier, who has been director for many years of the Assistance publique in the department of the Seine, in which Paris is situated, will retire shortly, having reached the age limit, and Mr. Serge Gas has just been appointed. The new director has for some time occupied an important administrative position in the public health ministry.

Successors to Charcot

The Academy of Sciences has just elected Dr. Louis Martin, director of the Pasteur Institute, as a fellow. He will thus be the successor of Prof. Jean Charcot, who died during a voyage of exploration in the arctic regions. Dr. Martin was associated with the late Professor Roux in the elaboration of the diphtheria antitoxin, became head of the serotherapy department of the Pasteur Institute in 1910 and was elected director of the institute after the death of Professor Roux.

At the May 5 meeting of the Academy of Medicine, Georges Duhamel was elected a fellow as successor to the late Prof. Jean Charcot. Duhamel is a physician but does not practice. He is one of the leaders in literary circles in France.

Professor Parisot Elected Chairman of Hygiene Committee

Prof. Jacques Parisot, head of the department of hygiene and preventive medicine at the University of Nancy, has been elected chairman of the committee of hygiene of the League of Nations. His predecessor was Dr. Madsen, director of the Royal Serologic Institute of Copenhagen, Denmark.

Marriages and Births Decrease

According to official statistics made public May 17 there were 279,743 marriages in 1936 as compared to 284,895 in 1935. The number of births likewise declined from 640,527 in 1935 to 630,059 in 1936. There were, however, fewer deaths, 642,139 in 1936 as compared to 658,379 in 1935.

BERLIN

(From Our Regular Correspondent)

May 22, 1937

Congress of the German Society of Surgery

The congress of the German Society of Surgery convened at Berlin during Eastertide under the presidency of Professor Stich of Göttingen, who in his address urged economy in the use of bandaging materials and of ligation materials such as catgut. He also advocated the greater utilization of domestic products as opposed to foreign imports for these purposes, cellulose as a cotton substitute, for example. The speaker deprecated the breaking away of special disciplines (neurosurgery, urology and so on) from surgery regarded as a whole.

K. H. Bauer, Breslau ordinarius, spoke on the advances of experimental cancer research. More than 24 per cent of the operations performed at his clinic are cancer operations. Many of the tumors produced experimentally in animals are highly malignant. The resistance and type specificity of the inoculated cells of the Brown-Pearce tumor, if contrasted with other cancer material, is astonishing, not only can these cells be used in successful autotransplantation but they will thrive when transplanted to a foreign animal organism. The pathogenesis of cancer in man is quite certainly dependent on from seven to eleven hereditary factors. In addition to the chromosomal inheritance, another important hereditary influence that acts through the protoplasm of the ova has a pathogenic role in cancer. If it is true that a latent predisposition to cancer is based on a combination of hereditary factors, it is equally true that external influences, painting with otherwise innocuous doses of tar, for example, favor the development of the disease. Besides, it is altogether probable that substances within the body (such as hormones) are capable of fostering a latent predisposition. In the pathogenesis and localization of cancer, hereditary factors doubtless play a part. In Bauer's opinion the transformation of normal body cells into cancer cells comes about through abrupt mutational alteration of the sum of hereditary factors. All those substances that are experimentally capable of inducing mutations are likewise cancerogenic, radioactive substances are a classic example of this phenomenon. If mutation is considered the crucial pathogenic factor in cancer, then, according to Bauer, it is reasonable to assume that by yet further mutation the cancer may be destroyed, this explains why roentgen rays both produce and cure cancer. Not infrequently skin carcinoma in man can be eradicated in an amazingly brief period by small doses of benzopyrine, one of the most powerful of cancerogenic agents. The treatment consists in part of painting, in part of injections.

Concluding the discussion of cancer, Ferdinand Sauerbruch of Berlin reported the results of his research. He believes that cancer in youthful persons is almost always coexistent with some type of sexual dysfunction, such as impotence or dysmenorrhea. Sauerbruch attributes the high incidence of the disease among elderly persons to the extinction of sexual function. In experiments with rats it was observed that, of sixty

castrated animals, nine developed spontaneous malignant tumors whereas, among forty not castrated, only one such tumor appeared. The author feels that this difference is based on the flooding of the normal organism with gonadotropic hormone from the anterior lobe of the hypophysis.

Much greater quantities of this substance are found in the urine following extirpation of the spleen. Perhaps a basis for the protection of splenic tissues from cancer is here suggested.

Introducing the next topic, the surgery of the brain, Schönbauer of Vienna pointed out that in the preparation for brain operations, as well as in conservative treatment of cranial traumas, a dietetic therapy which influences the water exchange will be important. After the clinic had established as a preparatory routine two or three salt-free days and the administration of theophylline with ethylene diamine just prior to the operation, there were no further instances of cerebral edema.

NATURE AND TREATMENT OF PSEUDARTHROSIS

At the second day's session the principal report was that of G. Magnus of Munich on the nature and treatment of pseudarthrosis. The speaker defined pseudarthrosis as a completed process that first becomes distinguished from retarded formation of callus when osseous healing fails to appear despite the termination of the other healing processes. The incidence of pseudarthrosis is not constant, it fluctuates between 0.5 and 5 per cent. With respect to etiology, three types of the disorder are to be differentiated: pseudarthrosis resulting from retarded callus formation, that resulting from defects of the bone and the so-called general pseudarthrosis. The origin of the first named type has not yet been satisfactorily explained. Known vitamins and hormones (latterly vitamin C in particular) have been collectively studied with reference to their influence on the formation of callus, since it has been observed that in the presence of hunger and scurvy even a healed fracture area may hinder the osseous healing and result in the formation of the false joint. The condition should in such cases be regarded as a symptom of fatigue. Accordingly, the treatment of a pseudarthrosis in a fracture of the neck of the femur consists of joining the fractured parts in such a way that no movement can tax the callus by false tension. This treatment promises much.

The role that is assumed by an extravasation of the blood in fractures is still a controversial matter, however, it has been observed that complete drainage of the extravasation in complicated fractures exercises a detrimental effect. Marginal necroses are likewise of importance. Magnus was able to demonstrate clinically that marginal necroses are in all probability to be interpreted as sequels of an injury produced by heat, as local temperatures in fracture cases may be as high as 48 C (118.4 F). Metallic foreign bodies may exercise harmful effects chiefly on the surrounding tissues. This is particularly likely to eventuate if combinations of metals are utilized, the metals tend to act as batteries and electrolytic disturbances are apt to result. Surgical treatment of pseudarthrosis consists chiefly of complete resection of the false joint and transplantation of a bone fragment, from the tibia, for example. Optimal results were obtained by the employment of this method. A few pseudarthroses are resistant to all types of treatment.

Professor Guleke of Jena discussed "The Limits of Surgical Responsibility." The successes of surgery have led the public constantly to demand more and expect more of the surgeon. This attitude has its repercussions in jurisprudence, since even the law has come to make unreasonable demands of the medical profession. An example is found in a recent decision of the supreme court whereby a physician is in duty bound to utilize all the most modern methods available for establishment of a diagnosis and is furthermore compelled, in cases in which surgical intervention is indicated, to acquaint the patient with the

exact nature of his illness and with all possible, even the most remote, dangers connected with the operation. Thus the judicial and the medical points of view may sometimes be at variance.

Sauerbruch of Berlin then spoke on the rarer causes of pulmonary hemorrhage as distinguished from more common causes such as tuberculosis, abscesses and infarcts. Hemorrhage may be traced to tumors and to vascular alterations such as varicosities in the region of the intercostal and pulmonary vessels. These varicosities are to be regarded as a result of chronic inflammations, for example, in gunshot injuries in which the missile remains in the organism, enlargement is brought about by the constant irritation of the vessels. Careful investigation has disclosed that in addition to capillary anastomoses between the pulmonary and bronchial arteries a direct medium sized anastomosis may exist between the two vessels, accordingly hemorrhage may originate in either region. Gross varicosities of the intercostal vessels can form direct anastomoses with the lungs and this condition constitutes a grave menace. A pressure or resection with a fragment of the lung may be a surgical indication.

IMPORTANCE OF VITAMINS TO SURGERY

A paper by Fromme of Dresden dealt with "The Importance of the Vitamins to Surgery." He pointed out that a diet which possesses a vitamin content sufficient under normal conditions may produce an avitaminosis because of increased consumption incident to certain diseases, and this deficiency may lead in turn to degenerative alterations in the reticulo-endothelial system. Fromme stressed as of special importance the loss of vitamin as a result of disease in the abdominal cavity and as a result of abdominal operations. Toxic impairment incident to gastro-enterostomies as well as high grade pyloric stenosis and many atonic conditions of the intestine can perhaps be traced to vitamin B₁ deficiency. If prolonged intravenous drip infusion of dextrose is carried on, it will be observed that the need of vitamin B₁ increases considerably with the increased supply of carbohydrate. Complete resection of the stomach can perhaps lead to hyperchromic anemias as the result of an obliteration of the antiperistaltic influences in the gastric wall. Such anemia can be treated only by liver, whereas the more frequent hypochromic anemias react well to iron. Many common kidney disorders following abdominal operations may perhaps be avoided if prior to the operation the organism is reinforced with vitamin C and if vitamin C is parenterally supplied during the postoperative period. Since it may be considered that ulcer diets contain too little vitamin C, they should be planned to include fruit juices. Ordinary hospital fare is as a rule deficient in vitamin, especially vitamin C, regardless of the fact that an increased need of vitamin is present in most diseases. In avitaminotic states the ability of the gastro-enteric canal to absorb the vitamin supply should be considered. Fromme also referred to an as yet uncertain interrelation of vitamin A and the pathogenesis of renal calculi. On this basis cod liver oil may be of value in the prophylaxis of recurrent calculi. Prolonged drainage of the bile ducts is to be cautioned against, as the procedure may lead to disturbances of the vitamin economy.

PHYSIOLOGIC BASES OF CIRCULATORY COLLAPSE

On the final day, Rein, Gottingen, physiologist, read an exceptionally well received paper on "The Physiologic Bases of Circulatory Collapse," which consisted chiefly of excerpts from his own works. According to the prevalent view, collapse consists not only in the failure of the heart but more notably in the failure of peripheral circulation, namely, a dysfunction of the reflux to the heart. In this state the heart is found to be diminished in size and the veins empty in contrast to the enlarged heart and venous congestion observed in cardiac failure. Modern physiology of the vascular system, however,

no longer distinguishes between heart and circulation and besides is closely linked with consideration of the local and general metabolism. By the term "circulatory regulation" is meant the ability quickly to restore at any time an equilibrium between the demands of metabolism and the vascular reserves. The healthy organism places a minimal burden on the heart in all circumstances, namely, normal blood pressure tends to maintain a decreased minute volume. If the heart is called on to meet the demands of physical exercise, the rate may increase to five or six times the normal but the blood pressure, conversely, is subject to relatively slight increase.

The vasodilatation of muscles at work is caused by local metabolic changes. Working musculature may demand as much as 2 liters of blood in excess of its requirement when at rest, thence arises the importance of reflex autoregulation of the circulation by emptying of the depots and contraction in the part at rest. If this regulation does not suffice, the organism possesses still another safety mechanism: the insufficient blood perfusion results in an accumulation of carbon dioxide and this substance exerts a vasoconstrictor effect on the working region, which is blocked against the irritation of the medulla oblongata. Disturbances that ensue in such a situation may lead to collapse. Vasodilatation by histamine, formerly held responsible for the occurrence of collapse, is just as well compensated as any other type of vasodilatation. The effect of histamine is quickly offset by reflex release of epinephrine. Accumulation of histamine cannot be a general cause of collapse. Experiments with a new substance, 1-oxyphenyl-2-methyl-amino propane, provide another explanation of the genesis of collapse. In contrast to epinephrine and related substances, the new substance decomposes slowly and at the same time exerts a constrictive effect on the venous vascular system. In experimental use it produces first an emptying of the peripheral depots, then an increase in minute volume and only finally a rise in blood pressure. Epinephrine, on the other hand, readily induces a rise in pressure by increasing the peripheral current resistance. In experimental collapse and administration of the new substance it was observed that the collapse was not of peripheral origin and that a disturbance of the regulatory mechanism had taken place elsewhere. So operation collapse too must differ fundamentally from artificial collapse induced by histamine. In like manner an impairment due to the use of peptone that resembles anaphylactic shock is a disorder of the regulatory mechanism and not a peripheral disturbance.

For the practical treatment of collapse it is accordingly most important that substances such as epinephrine and ephedrine induce an increase in the peripheral current-resistance only, namely, they bring about a purely symptomatic increase in blood pressure. If it is postulated that through collapse a passive congestion of the lungs has already taken place, it is clear that an increase in the outer blood pressure by this means can have as its consequence acute cardiac failure. Besides, new investigations of Professor Rein's have demonstrated that epinephrine increases the oxygen requirements of the heart and thus reduces the functional capability of the myocardium. Finally Rein pointed out that in experimentation, despite blood pressure increase by epinephrine and related substances, the minute volume of the heart increased not at all and, as a result of this, after cessation of the effect of pressure the entire function of circulation will be even more impaired than before. According to Rein's observations, any narcosis may produce a situation quite favorable to collapse as a result of a reduction of the reflex regulation. At the remission of a narcosis the danger of collapse is particularly great, as the awakening of the organism imposes increased demands on the badly functioning circulation.

In conclusion, another contribution needs to be mentioned, that of Dr. Adler of Berlin, who was able, by repeated transplantations of thymus tissue as well as by injections of hydrous

thymic extract, to induce a classic clinical myasthenia in dogs. As in man, so in these experiments the entire syndrome could be abolished almost immediately by injections of prostigmin, only to appear again some six hours later. These tests supplement various observations of the coincidence of thymic hyperplasia and myasthenia. It may be possible to cure a severe myasthenia by removal of a hyperplastic thymus.

Surgical Treatment of Cataract

Prof. Hermenegildo Arruga of Barcelona, in a lecture delivered in São Paulo, spoke on the surgical treatment of cataract. Total removal of the cataract is, according to the speaker, a better operation than extracapsular removal. The patients regain a clear sight after the operation and there is no danger of recurrence. The period of incapacity of the patient for work is short because of the fact that total extraction can be performed at a time when the patient is still working with a fairly good sight. The number of patients who decide for the operation is larger when they know that they do not have to wait for complete maturation of the cataract. The speaker advised a moderate dilation of the pupil before the operation. Induction of retrobulbar anesthesia is important. It diminishes pain, the globular tension and the contracture of the rectus muscles of the eye during the operation and also retards the appearance of pain afterward. The incision at the cornea has to be ample in relation to the horizontal diameter of the eye, beginning at the sclera and then following a slightly upward course to the opposite side of it.

Measuring the Diameter of the Aorta

Dr. Agunello Lins of Recife, taking as a basis the work of Dr. Manoel de Abreu on x-ray visualization of the mediastinum, calculated the diameter of the lumen of the aorta at the arch. Three points are marked at any place at the arch, which are then joined by two straight lines. Perpendicular lines are then drawn from the central point of the lines, centrad to the inside of the arch. The point of intersection of the perpendicular lines is the center of the lumen. The length of a line drawn from the center of the lumen to any point at the arch is the radius. Twice the length of the radius is the diameter of the lumen of the aorta at the level of the arch. The author made a study of comparison between the geometrical and the intertracheopulmonary measures. There is a difference in these measures of 1.5 mm, which is given by the thickness of the tracheal wall. Measuring the lumen of the aorta by this method has been done also by Professor Lian of Paris for the last year.

Colony for Lepers

New pavilions will be open to lepers in the colony of Itan-henga in the state of Espirito Santo in April. During 1935 thirteen pavilions were opened to lepers in the colony. The addition of the new ones solves the problem of leprosy in that part of Brazil, where 675 lepers are registered. The colony has large camps for agriculture and the breeding of animals, which helps to keep the lepers happy in their isolation.

Monument to Couto

A monument is to be erected in the near future in memory of Prof. Miguel Couto, who was president of the Academia Nacional de Medicina for twenty years. His professional life and work are full of good examples. Prof. Aloysio de Castro is the president of the committee in charge of construction and dedication of the monument.

Personal

Dr. Lincoln Araujo, Brazilian surgeon and gynecologist, was appointed a member of the editorial staff of the journal *Surgery Gynecology and Obstetrics* of Chicago.

Congress of Chemistry

The second Brazilian Congress of Chemistry was held in Rio de Janeiro in May. The organizing committee works for the success of the congress. A large attendance is expected. Brazilian chemists are writing to the organizing committee that they are ready to collaborate. The topics will deal with the most important branches of chemistry and technology, as well as with several industrial, social and legal problems related to chemistry. Technical committees are already appointed. There will be an exposition.

New Building of the General Polyclinic

The poor of Rio de Janeiro have received free medical care for about fifty-five years at the Policlínica Geral of that city. The building was erected in 1882. Regular work was done in fourteen clinics. At present the number of patients exceed the accommodations of the building. The corner stone for a new twelve story building was recently dedicated. Postgraduate courses will be given also. The board of directors of the polyclinic has received liberal donations for the construction of the new building.

BUENOS AIRES

(From Our Regular Correspondent)

April 30, 1937

New Building of Faculty of Medicine

The project for construction of a new building for the Faculty of Medicine at a cost of 12,000,000 pesos (\$3,500,000) was approved by the government. Plans for the arrangement of the several class rooms are in revision. The faculty reduced its quarters to three fourths of its former space. The class rooms and amphitheatres are now insufficient. The government asked the university to cut down expenses by 12 per cent. The university is requesting the same allowance for expense that it had in 1930, which was cut down from that year up to the present by 47 per cent.

Donations for Scholarships

Mr Esteban Peruhil has donated 2,000,000 pesos (\$580,000), of which the interest is to be used for scholarships for postgraduate medical studies in foreign countries. Other Argentine scholarships for postgraduate studies in foreign countries are the Bartolome Devoto and the Sauberman (with \$2,200 and \$1,500 a year, respectively) and those of the Comision Nacional de Cultura (\$2,350 a year) and of the Asociacion Argentina para el Progreso de las Ciencias (\$2,200 a year). There are also several scholarships for physiologic and other researches in the country. The government gave a donation to the Asociacion Argentina para el Progreso de las Ciencias of 1,000,000 pesos (\$290,000) to use the interest in research work made by Argentines in foreign countries.

Personals

The physicians of the hospitals filed a claim with the city government asking that the twenty vacancies at municipal hospitals for assistant physicians be filled by examination as provided by hospital regulations. The city made the appointments without examinations, and the physicians who filed the claim were requested to resign. It seems probable that a conflict may occur between the body of municipal physicians and the city government.

Drs Jose Arce, the dean of the Faculty of Medicine, A Landivar, A Egües, Castillo Odena, Alfredo Sordelli, Cossio, Meana A Pavlovsky, Bozzola and Garcia were recently in the United States. The interest of Argentine physicians in visiting American clinics, hospitals and universities is growing and it is probable that more visitors will be there during this and the coming year.

Dr G Marañon, Spanish professor and endocrinologist, gave a course of literary and medical lectures in Buenos Aires recently.

Marriages

HAROLD WELLINGTON JONES, Colonel, M.C., U.S. Army, Washington, D.C., to Mrs. Mary Morrison Camper of Charlottesville, N.C., in Arlington, Va., May 1.

JOHN HILLYER BOYD, New York, to Miss Elizabeth Gilmore Locke of Williamstown, Mass., May 8.

MORRIS THEODORE FRIEDEL, Minneapolis, to Miss Barbara Mantel Fishbein of Chicago, July 3.

KIRBY D. SHEALY, Columbia, S.C., to Miss Harriet Elsbeth Way of Cheraw, February 17.

HERBERT JUNIUS FOX, Franklinville, N.C., to Dr. Frances Faison Hill of Durham, May 15.

NORBERT G. RAUSCH to Miss Margaret D. Morrison, both of Buffalo, April 7.

Deaths

Dwight Howe Trowbridge of Fresno, Calif., Tulane University of Louisiana Medical Department, New Orleans, 1893, past president of the Fresno County Medical Society, member of the American Laryngological, Rhinological and Otolaryngological Society and the Pacific Coast Oto-Ophthalmological Society, fellow of the American College of Surgeons, one of the founders, secretary, and on the staff of the Burnett Sanitarium, was examiner for the aeronautics branch of the department of commerce, aged 66, died, May 4, in Pasadena, of bronchopneumonia.

Lewis McFarland Gaines of Atlanta, Ga., Johns Hopkins University School of Medicine, Baltimore, 1903, formerly associate professor of neurology and psychiatry, Emory University School of Medicine, professor of anatomy and physiology, Wake Forest (N.C.) College School of Medical Sciences, 1905-1908, on the staff of the Georgia Baptist Hospital, visiting physician on the staff of the Emory University (Ga.) Hospital, aged 59, died, May 24, of coronary thrombosis.

Harry Lawrence Hall, East Orange, N.J., University of Michigan Department of Medicine and Surgery, Ann Arbor, 1893, served in various capacities on the faculties of the University of Southern California, Los Angeles, Western Reserve University School of Medicine, Cleveland, Boston University School of Medicine and Emory University (Ga.) School of Medicine, aged 64, died, April 22, in the Orange Memorial Hospital, of cerebral hemorrhage.

George Paul Katzenstein, Chicago, University of Pennsylvania Department of Medicine, Philadelphia, 1900, formerly instructor on diseases of the skin, Philadelphia Polyclinic, at one time on the staffs of the John B. Stetson Hospital and the Jewish Hospital, Philadelphia, aged 63, died, April 22, of cerebral hemorrhage and chronic nephritis.

William Wheelock Lazarus of Tunkhannock, Pa., University and Bellevue Hospital Medical College, New York, 1902, past president of the Wyoming County Medical Society, member of the House of Delegates of the American Medical Association in 1932, served during the World War, aged 58, died, April 1, of coronary thrombosis.

Myron Stephen Gregory, Oklahoma City, University of Michigan Department of Medicine and Surgery, Ann Arbor, 1906, member of the Oklahoma State Medical Association, American Psychiatric Association and the Central Neuro-psychiatric Association, served during the World War, aged 67, died, April 9, of coronary occlusion.

Eleanor Bridge Kilham, Beverly, Mass., Woman's Medical College of the New York Infirmary for Women and Children, New York, 1882, was twice decorated by the French government for her services during the World War, at one time a practitioner in New York, aged 79, died, April 5, of coronary sclerosis and hypertension.

Charles Long, Wilkes-Barre, Pa., Jefferson Medical College of Philadelphia, 1882, member of the Medical Society of the State of Pennsylvania, for many years a member of the school board, on the staff of the Wilkes-Barre General Hospital, on the courtesy staff of the Mercy Hospital, aged 75, died, April 7.

Walter Weldon Harloe, Matoaka, W. Va., University of Virginia Department of Medicine, Charlottesville, 1905, member of the West Virginia State Medical Association, bank president, at various times mayor, chief of the fire department and health officer, aged 62, died, April 17, of coronary occlusion.

George William Haskins, Chicago, Chicago Medical College, 1889, professor of metallurgy, 1891-1892, and professor of metallurgy and of prosthetic technic, 1892-1897, Northwestern University Dental School, also a dentist, aged 78, died suddenly, April 30, of chronic myocarditis

Jeremiah Dumas Malone, Marietta, Ga., University of Maryland School of Medicine, Baltimore, 1884, past president of the Cobb County Medical Society, at various times member of the city council and board of education, was president of the county board of health, aged 76, died, April 11

Charles C Hickman, Logansport, Ind., Medical College of Indiana, Indianapolis, 1902, member of the Indiana State Medical Association, on the staffs of the Cass County Hospital, Logansport State Hospital and St Joseph's Hospital, aged 64, died, April 4, of heart disease

Morris David Hartman, Homestead, Fla., Jefferson Medical College of Philadelphia, 1912, member of the Florida Medical Association, served during the World War, aged 48, died, April 13, in Miami, of cerebral hemorrhage due to a head injury received in an automobile accident

Darwin Oliver Lyon, Mount Vernon, N. Y., New York Homeopathic Medical College and Flower Hospital, New York 1912, served during the World War, aged 49, died April 14, in the Grasslands Hospital, Valhalla, of pulmonary tuberculosis and tuberculous peritonitis

Laura Mann Johnson, Boston, Woman's Medical College of Pennsylvania, Philadelphia, 1906, member of the State Medical Society of Wisconsin, aged 61, died, April 2, in the Peter Bent Brigham Hospital, of carcinoma of the thyroid with extensive metastases

John Greenleaf Whittier Knowlton, Exeter, N. H., Harvard University Medical School, Boston 1900, member of the New Hampshire Medical Society, served during the World War, aged 63, died, April 17, in the Exeter Hospital, of cerebral hemorrhage

Frederick Austin Hunt, Pompey, N. Y., Syracuse University College of Medicine, 1898, member of the Medical Society of the State of New York, county clerk, veteran of the Spanish American and World wars, aged 61, died, April 9, of angina pectoris

Christopher H Johnston, Lexington, Tenn., University of Nashville Medical Department, 1890, member of the Tennessee State Medical Association, aged 72, died April 1, in the Webb-Williamson Hospital Clinic, Jackson, following an operation for gallstones

Arthur Herbert Haney, Oklahoma City, University of Oklahoma School of Medicine, Oklahoma City, 1927, member of the Oklahoma State Medical Association, served during the World War, aged 41, died, April 19, of pulmonary tuberculosis

William Francis Grubbs, Hazel, Ky., University of Nashville (Tenn.) Medical Department, 1898, member of the Kentucky State Medical Association, for many years a member of the school board, aged 71, died, April 2, of coronary thrombosis

Frank Charles Klein, Indianapolis, University of Indianapolis Medical Department, 1903, member of the Indiana State Medical Association, aged 63, on the staff of St Francis Hospital, where he died, April 22, of arteriosclerosis and diabetes mellitus

Gross Ransom Long, Nashville, Tenn., Vanderbilt University School of Medicine, Nashville, 1919, on the staffs of the Nashville General Hospital and Protestant Hospital, aged 46, died, April 19, of chronic nephritis and malignant hypertension

Calvin E Helffrich, Fogelsville, Pa., Hahnemann Medical College of Philadelphia, 1880, New York Homeopathic Medical College, 1881, aged 76, died, April 15, in the Allentown (Pa.) Hospital, of chronic myocarditis and hypostatic pneumonia

Elmer Alfred Gunderson, Elgin, Ill., Bennett College of Electric Medicine and Surgery, Chicago 1915, served during the World War, aged 44, on the staff of the Veterans Administration Facility, Hines, where he died, April 28, of pneumonia

Joseph Neree Lalonde, Providence, R. I., Laval University Faculty of Medicine, Quebec, Que., Canada, 1904, member of the Rhode Island Medical Society, aged 59, died, April 3, in the Jane Brown Memorial Hospital, of diabetes mellitus

Benjamin Franklin Janes Jr., Northampton, Mass., Tufts College Medical School, Boston, 1908, served during the World War, on the staff of the Cooley-Dickinson Hospital, aged 51, died suddenly, April 17, of coronary thrombosis

Roberts Bartholow Hays, Birmingham, Ala., Birmingham Medical College, 1913, fellow of the American College of Surgeons, on the staff of the Norwood Hospital and Clinic, aged 52, died, April 29, of acute coronary occlusion

Aubrey Vernon Jones, Louisville, Ky., Kentucky University Medical Department, Louisville 1906, served during the World War, aged 56, died, April 5, in the Veterans Administration Facility, Lexington, of heart disease

Frederic Clinton Hart, Girard, Pa., Western Reserve University Medical Department, Cleveland, 1892, member of the school board for many years, aged 74, died, April 25, in the Hamot Hospital, Erie, of cardiac hypertrophy

Joseph William Gothard, Holbrook, Ariz., Tennessee Medical College, Knoxville, 1891, formerly city physician of Palisade, Colo., aged 75, died, April 16, in Whittier, Calif., of rheumatic endocarditis and lobar pneumonia

Joseph Bernard Guitinan, West Rutland, Vt., University of Vermont College of Medicine, Burlington, 1904, member of the Vermont State Medical Society, aged 60, died, April 14, in the Rutland (Vt.) Hospital, of heart disease

Henry John Harp, Sussex, N. J., University of Pennsylvania Department of Medicine, Philadelphia, 1904, served during the World War, on the staff of the Alexander Linn Hospital, aged 55, was found dead, April 7

Oliver Nixon Huff, Fountain City, Ind., University of Michigan Department of Medicine and Surgery, Ann Arbor, 1878, member of the Indiana State Medical Association, aged 85, died, April 23, of heart disease

Ermine Stevenson Cryder, Cleveland, Starling-Ohio Medical College, Columbus, 1913, member of the Ohio State Medical Association, formerly on the staff of the Woman's Hospital, aged 49, died, April 23

James M Haney, Centralia, Ill., Northwestern University Medical School, Chicago 1897, member of the Illinois State Medical Society, aged 73, died, April 20, in St Mary's Hospital of carcinoma of the lung

Vincent John Fenerty, Philadelphia, University of Pennsylvania Department of Medicine, Philadelphia, 1908, served during the World War, aged 51, died, April 15, in the Methodist Episcopal Hospital

Douglas Largen, San Antonio, Texas, Vanderbilt University School of Medicine, Nashville, Tenn., 1906, served during the World War, aged 54, died, April 19, in the Medical Arts Hospital, of pneumonia

John C Jacobs, Miami, Okla., Barnes Medical College, St. Louis, 1903, past president of the Ottawa County Medical Society, served during the World War, aged 67, died, April 2, of coronary thrombosis

John Donald MacDonald, Ingersoll, Ont., Canada, Western University Faculty of Medicine, London, 1906, aged 58, was drowned, April 26, when his car was washed over a bridge near Beachville by a flood

Joseph Alexander Bell, Sarnia, Ont., Canada, Western University Faculty of Medicine, London, 1897, formerly mayor, health officer of Sarnia, aged 67, was found dead in bed, April 12

Levi White Hunt, Toledo, Ohio, Ohio Medical University, Columbus, 1903, veteran of the Spanish-American War, aged 66, died, April 7, of heart block, infected teeth and diabetes mellitus

Frank T McClintic, Marlinton, W. Va., Medical College of Virginia, Richmond, 1887, formerly bank president, died, April 15, in the Pocahontas Memorial Hospital, of heart disease

George A Humpert, St. Louis, St. Louis Medical College, 1884, member of the Missouri State Medical Association, aged 75, died, April 16, of chronic myocarditis and arteriosclerosis

Robert Lowell Mason, Trenton, N. J., Howard University College of Medicine, Washington, D. C., 1932, aged 41, died, April 12, in the Mercer Hospital, of cardiac decompensation

Henry Hein, Wilber, Neb., John A. Creighton Medical College, Omaha 1903, president of the Saline County Medical Society, aged 59, died, April 24, of congestive heart disease

Edward Carroll Alvis, Benton, Ill., St. Louis College of Physicians and Surgeons, 1905, member of the Illinois State Medical Society, aged 66, died, April 30, of hypernephroma

John F McCarty, Oxett, Miss., Tulane University of Louisiana Medical Department, New Orleans, 1892, aged 71, died in April, in a hospital at Laurel, of pneumonia

Joseph G Gray, Franklin, Ky., University of Tennessee Medical Department, Nashville, 1899, member of the Kentucky State Medical Association, aged 60, died, April 13

Chalmers Nash Kendrick, Buffalo, Chicago Homeopathic Medical College, 1898, aged 64, died, April 18, in the Millard Fillmore Hospital, of arteriosclerosis and uremia

Clarence Dupree Jones, Hillsboro, N. C., Vanderbilt University School of Medicine, Nashville, Tenn., 1887, aged 70, died, April 3, of angina pectoris

Alphonse Denis Fouchy, La Mesa, Calif., Hahnemann Medical College, San Francisco, 1887, aged 79, died, April 7, of myocarditis and diabetes mellitus

Henry Covington Macy, Chicago, Bellevue Hospital Medical College, New York, 1897, aged 70, died, April 2, of chronic myocarditis and bronchopneumonia

Alvin Bernard Stone, The Dalles, Ore., University of Oregon Medical School, Portland, 1902, aged 59, died, March 29, in a hospital at Pendleton

Benjamin H. Bennett, Dallas, Texas, University of Tennessee Medical Department, Nashville, 1895, aged 74, died, April 9, in a local hospital

Lee Johnson, Gastonia, N. C., Jefferson Medical College of Philadelphia, 1911, aged 49, was found dead, April 8, of a self-inflicted bullet wound

Royal William Grubbs, Gary, Ind., Meharry Medical College, Nashville, Tenn., 1916, served during the World War, aged 51, died, March 14

Harry John Herman, Jerseyville, Ill., Northwestern University Medical School, Chicago, 1933, aged 34, died, April 15, of lobar pneumonia

J. A. Hector Forgues, Montreal, Que., Canada, Laval University Medical Faculty, Montreal, 1911, aged 51, died suddenly, March 25

Oliver Bagby, Vinita, Okla., University of Missouri School of Medicine, Columbia, 1881, formerly bank president, aged 78, died, April 20

William H. Coontz, Findlay, Ohio, Medical College of Ohio, Cincinnati, 1899, aged 70, died, April 3, of carcinoma of the prostate

Charles B. Watkins, Clinton, Miss., Louisville (Ky.) Medical College, 1906, aged 70, died, March 20, in a hospital at Jackson

Harry John Quinn, Mount Pleasant, Ont., Canada, University of Toronto Faculty of Medicine, 1920, aged 45, died, March 25

Thomas C. Rogers, Wellston, Ohio, Miami Medical College, Cincinnati, 1869, Civil War veteran, aged 87, died, March 19

Morley Cuthbert Salmon, Victoria, B. C., Canada, University of Toronto Faculty of Medicine, 1911, aged 51, died, March 29

George Chauncey Leach, Toronto, Ont., Canada, Queen's University Faculty of Medicine, Kingston, 1904, aged 60, died, April 19

Richard Leffers, Lakeland, Fla., University of Tennessee Medical Department, Nashville, 1909, aged 59, died suddenly, April 12

John Eldon Craig, Ottawa, Ont., Canada, McGill University Faculty of Medicine, Montreal, Que., 1899, died, April 7

John Roscoe Young, Mattoon, Ill., Eclectic Medical Institute, Cincinnati, 1888, aged 85, died, March 23, of uremia and nephritis

C. E. Leatherman, Louisville, Ky., Kentucky School of Medicine, Louisville, 1898, aged 73, died, April 15, of heart disease

Miles Jasper Wilhoit, Water Valley, Miss., Memphis (Tenn.) Hospital Medical College, 1913, aged 54, died in March

James Blainie Hall McClinton, Midland, Ont., Canada, Trinity Medical College, Toronto, 1888, aged 78, died, April 12

William J. Lankford, Chanute, Kan., Northwestern Medical College, St. Joseph, Mo., 1892, aged 85, died, in April

Marshall Bidwell Ketchum, Los Angeles, Eclectic Medical Institute, Cincinnati, 1882, aged 80, died, April 17

Edward Merriett Watkins, Sacramento, Ky., Louisville Medical College, 1882, aged 80, died, March 30

George Carl Lotz, New York, Bellevue Hospital Medical College, New York, 1896, aged 64, died, April 30

Henry Franklin Massie, Haverhill, Ohio, Miami Medical College, Cincinnati, 1896, aged 69, died in April

James N. Baxter, Berlin, Tenn., University of Nashville Medical Department, 1878, died in April

Correspondence

FORTY DAYS' CONSTIPATION

To the Editor—A few years ago while in charge of a large hospital in South China I saw a man whose bowels had not moved for forty days. The Chinese are very reliable in giving clinical histories and taking a great deal of notice of their excretory functions. I believe implicitly that the man's statement that his bowels had not moved for forty days was no exaggeration.

He was addicted to opium, which has a constipating effect. When he came to the hospital he was so weak that he was unable to walk and had to be carried. As a result of the toxic effect of this prolonged gastro-intestinal stasis his eyesight had become seriously impaired and there was a peculiar milky appearance of the cornea. Enemas were not effective and it was necessary to remove the fecal impactions manually. Following this procedure the patient was given daily cathartics for a time and his eyesight improved and his physical strength returned.

This is a rather extreme case of intestinal auto-intoxication and is cited in the hope that it may cause others who have come in contact with cases of prolonged obstipation to cite their experiences, as I have never seen an account of such prolonged and obdurate stasis.

WILLIAM K. McCANDLISS, M.D.

New Jersey State Hospital, Trenton, N. J.

REPRODUCTIVE PERFORMANCE IN MAN

To the Editor—In an editorial in *THE JOURNAL*, May 22, "Reproductive Performance in Man" is the statement "she would produce as an average 33 births."

My genealogy is so complete that I know practically all the births on both sides to 1697 and on my maternal side for hundreds of years more. I once tabulated, for each twenty-five year marriage, the number of births to a marriage. It was uniformly, if I now remember correctly, 34, until I went back of 1600, when it began to vary for lack of sufficient data. Families were no larger in the 1700s than today. Some had eight or ten children, many, as today, had none.

I have used these figures to combat the birth control idea. The average woman, with no prevention, will have an average of 34 births. This just covers the losses from deaths in infancy and keeps the population nearly uniform.

RAWLINS CADWALLADER, M.D., San Francisco

GANGRENE OF THE SKIN

To the Editor—I was much interested in the editorial in *THE JOURNAL*, May 29, on progressive postoperative bacterial synergistic gangrene of the skin caused by the synergistic action of the nonhemolytic micro-aerophilic streptococcus and *Staphylococcus aureus*. This condition has been frequently confused with the chronic undermining burrowing ulcers in which the hemolytic micro-aerophilic streptococcus is the sole causative organism.

A number of articles have appeared which have confused these two conditions and it is important to differentiate clearly between them. In both, zinc peroxide is now an established method of treatment after excision, as I stated in a paper that appeared in the *Surgical Clinics of North America* in June 1936.

In the gangrenous cases, wide excision is essential and recovery will occur after excision alone, but zinc peroxide prevents recurrence, hastens the healing and permits skin graft.

ing earlier than would otherwise be the case. In the undermining ulcer type, excision is sometimes not necessary because there is no gangrene, and frequently zinc peroxide can be brought into close apposition with the surface of the infection without extensive operation.

FRANK L. MELENEY, M.D., New York

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

BISMUTH COMPOUNDS IN THE TREATMENT OF SYPHILIS

To the Editor—I should like to ask your advice concerning the use of bismuth compounds in the treatment of syphilis. Stokes (in his 1934 edition, page 251) emphasizes the use of Lomholt's rule, which calls for a dosage of 0.5 mg of bismuth per kilogram of body weight per day. This would amount to 245 mg per week for an adult weighing 70 kg. Elsewhere in the same reference he advises a dose of from 2 to 2.3 Gm of bismuth metal per ten weekly injections or about 200 to 230 mg per week. Schwartz (*Ann Inst Pasteur* 45:386 [Sept] 1930) reports that until 1927 the dosage used at the Fournier clinic was 240 mg of sodium and potassium bismuth tartrate per week. Since 1927 the dosage has been 160 mg of oil-soluble bismuth per week. Naturally various factors other than weight such as age, kind of syphilis, preparation employed, and evidence of toxicity affect the dosage. The dosage recommended for the various preparations in New and Non-official Remedies is much less than these amounts, however. For example, bismocymol 100 mg per week, bismuth sodium tartrate 90 mg per week and oleo-bi-Roche 100 mg per week. 1. Do you think that Lomholt's rule is a reliable guide in estimating dosage? If so, are not the dosages recommended in New and Non-official Remedies too small? 2. Should the oil suspension preparations of bismuth be for the most part discarded as suggested by many recent authorities? 3. In the French clinics where bismuth is the only drug employed (as in the Fournier clinic) and where injections are given twice weekly for twelve weeks, what is the best period used? 4. What is the metallic bismuth content of 120 mg of bismuth salicylate? Please omit name.

M.D. California

ANSWER—1. Lomholt, working with an aqueous suspension of bismuth oxychloride, suggested a dosage of 5 mg of metallic bismuth per kilogram of body weight per day. This preparation is comparatively well absorbed and excreted. Naturally, this advice could not safely be used with a preparation such as bismuth salicylate, of which there is such a slow absorption and consequent excretion in the urine and feces. After all, what is desired with all bismuth preparations is the absorption from the injection site of sufficient bismuth to make a continuous therapeutic level in the blood stream, which will be measured in terms of bismuth excretion in the urine and feces, particularly the urine. If one is employing an aqueous solution, naturally this will mean injections two or three times a week to keep this bismuth level at the proper height. With a water or oil suspension of an insoluble preparation or with an oil soluble preparation it may be possible to achieve this with an injection but once a week, and if the preparation shows a comparatively continuous daily excretion of from 2 to 4 mg of metallic bismuth in the urine this is an excellent indicator of therapeutic effect of the preparation and is much more satisfactory than a hard and fast rule such as the one proposed by Lomholt, which might apply for certain preparations and which, on the other hand, would be inappropriate for certain other preparations. It is our belief that the dosages recommended for N. N. R. are worked out more on the idea of a therapeutic level in the blood stream. This can be attained with bismocymol, 100 mg injected once a week, with tri-weekly injections of bismuth sodium tartrate. Kurthy (*Biochem Ztschr* 150:173 1924) reports that in a patient who received treatment with fifteen injections of oleo-bi-Roche from November to January, excretion studies made ten days later showed amounts starting with 184 mg of bismuth, reaching a height of 547 mg January 29, and dropping to 138 by February 2.

2. We see no reason why oil suspension preparations of bismuth should be discontinued, except for the fact that they are more costly than other preparations.

3. In certain of the French clinics bismuth alone is employed, at least, in the Fournier clinic. Far better results can probably be achieved with continuous therapy with alternating courses of arsenicals and bismuth.

4. Injections of bismuth subsalicylate in oil are generally employed in doses of 1 or 2 cc of a 10 per cent suspension. There is 65 mg of metallic bismuth in 1 cc and 130 in 2 cc of the suspension.

USE OF MASSIVE DOSES OF VITAMIN D

To the Editor—What is the present status of treatment with massive doses of vitamin D? What is an excessive dosage? Have there been any pathologic studies on those who have been treated with massive doses of vitamin D? What conditions contraindicate the use of massive doses? Please omit name and address.

M.D. Arizona

ANSWER—Massive doses of vitamin D have been used with varying success for a number of clinical conditions such as parathyroid tetany, pollinosis and tuberculosis, but it is assumed that the inquiry refers to its use in treating arthritis. In their original publication Dreyer and Reed (*Arch Phys Therapy* 16:537 [Sept] 1935) reported only limited success and admitted that it cannot be considered a cure. Their experience extended over a period of three years and included 120 cases. Vrtiak and Lang (*THE JOURNAL*, April 4, 1936, p 1162), in a series of twenty-two cases for the duration of one year or less, took a rather conservative view, stating that other measures were of equal value, a position freely admitted by Dreyer and Reed. In recent addresses before a hospital staff, Vrtiak expressed a somewhat more enthusiastic view.

Livingston (*Arch Phys Therapy* 17:704 [Nov] 1936) has enthusiastically endorsed this method on the basis of treatment of twenty-two cases for a year or less. Farley (*Illinois M J*, to be published) also has taken an enthusiastic stand regarding this form of therapy. On the other hand, Wyatt, Hicks and Thompson (*Ann Int Med* 10:534 [Oct] 1936) have reported indifferent results in forty cases. The duration of treatment was not stated. Lautman, in an address before the Chicago Medical Society, Dec 16, 1936, stated that "vitamin D concentrates are helpful when indicated, although the claims made for their use in massive dosage have not as yet been established."

An excessive dose is a relative matter that can be determined only by trial. Some individuals are reported to have tolerated well for considerable periods daily doses as high as 30,000 international units per kilogram of body weight. Others are sensitive to doses as low as 5,000 units per kilogram daily for only a few days. However, these responses appear not to be true hypervitaminosis D but rather gastro-intestinal sensitivity to the solvent. This is not, however, a settled question. If any symptoms suggestive of overdosage appear, the only safe procedure is to discontinue the treatment. The symptoms have been described in several publications (Reed, C. I. Symptoms of Viosterol Overdosage in Human Subjects, *THE JOURNAL*, May 26, 1934, p 1745; Dreyer and Reed, already cited; Shelling, D. H. The Parathyroid Glands in Health and Disease, St. Louis: C. V. Mosby Company, 1935; Crimm, P. D., and Strayer, J. W. *Am J M Sc* 187:557 [April] 1934; Crimm, P. D., Strayer, J. W., Watson, H. L., and Heimann, G. *Am Rev Tuberc* 28:202 [Aug] 1933; Crimm, P. D., and Strayer, J. W. *J Lab & Clin Med* 19:966 [June] 1934).

Contraindications are any kidney disturbance, coronary disease and persistent intolerance to any dosage.

Pathologic studies in human subjects are few because few patients so treated have come to necropsy. Shelling and Jackson (*Bull Johns Hopkins Hosp* 55:314 [Nov] 1934), Thatcher (*Lancet* 1:20 [Jan 4] 1936) and Ravina (*Presse med* 44:1471 [Sept 19] 1936, abstr. *Internat M Digest* 24:359 [Dec] 1936) have made the most recent reports. Cowdry and Scott (*Arch Path* 22:1 [July] 1936) have reported in great detail the results of experimental studies in monkeys. It is understood that another extensive report on the pathology of vitamin D will appear in an early issue of the *Annals of Internal Medicine*.

Available information at present indicates that so long as no clinical symptoms of toxicity appear there are no permanent changes of pathologic nature in the tissues. However, much more work must be done to settle this question.

The public press late in March 1936 carried a story of the death of an aged physician in San Francisco who attempted self medication but miscalculated the dose. The immediate cause of death was unquestionably hypervitaminosis D, but the dose was far in excess of any recommended for arthritis.

It would appear, therefore, that the use of vitamin D must depend on the judgment of the physician as to whether the unpredictable but possible benefits offset dangers that are at present largely theoretical if all precautions are observed.

The position of the Council on Pharmacy and Chemistry on the use of very high potency vitamin preparations in arthritis appeared in a report in *THE JOURNAL*, May 16, 1936, page 1732. Elsewhere in this issue (p 132) is a report by the Council on two such preparations: Condol and Ertron.

ARSPHENAMINE JAUNDICE IN SYPHILIS OF THE
NERVOUS SYSTEM

To the Editor—May I ask your suggestions concerning continued treatment for a case of cerebrospinal syphilis? I first saw the patient, a man of 37, Oct 15, 1935, when he was suffering a severe hemolytic jaundice which appeared after he had received eight intravenous doses of 0.06 Gm of neoarsphenamine during the preceding two months. Continuous vigorous treatment over a period of four months relieved the jaundice with its marked generalized pruritus, the patient gaining weight and enjoying a great improvement in general health. Several months treatment with soluble bismuth intramuscularly was given. Antedating the treatment with neoarsphenamine the patient's blood Wassermann reaction was four plus but all subsequent blood Wassermann reactions (even after three months rest from all treatment) have been negative. Recently mental and nervous symptoms have become evident and a spinal fluid Wassermann reaction is four plus in 0.5, 0.25 and 0.125 cc dilutions. There is a spinal fluid cell count of 1. The globulin test is negative. The colloidal gold curve is not typical. I feel that the patient's condition urgently suggests trypanamide but in view of his extremely serious experience with neoarsphenamine I hesitate to administer any arsenical. I have decided to administer a bismuth compound intramuscularly continuously but doubt whether it is sufficient. Please omit name.

M D, New Mexico

ANSWER—Postarsphenamine jaundice is not hemolytic but obstructive and is due to diffuse (presumably toxic) hepatitis. It does not usually persist for a period of four months. When jaundice occurs in a syphilitic patient under treatment with the arsenical drugs, it must be remembered that it may be due to any one of many other causes than syphilis or treatment.

The correspondent does not state the character of the mental and nervous disturbances that have recently become evident and, although the spinal fluid Wassermann reaction is positive, the remaining conditions in the spinal fluid are not typical of dementia paralytica. If, however, the diagnosis of dementia paralytica is justified on physical and psychiatric grounds, the treatment urgently indicated at the outset is artificial fever with induced malaria, which should be given before any other form of treatment is attempted. When the malaria is completed, trypanamide may be used without fear of repetition of the jaundice, but of course with due caution as to visual reactions.

The mechanism of production of postarsphenamine jaundice is not clear, but it is certainly not a sensitization phenomenon, such as is postarsphenamine dermatitis. Most patients who have been jaundiced following some of the arsphenamines may, after recovery from the jaundice, be treated again even with the same arsphenamine preparation which apparently precipitated the reaction originally. While treatment jaundice does occur after trypanamide, it is much rarer than with the arsphenamines and a recurrence of the reaction is not likely.

If the diagnosis of dementia paralytica in this patient is correct, prolonged bismuth treatment is completely inadequate.

FISH POISONING OR ERYSIPELOID

To the Editor—Is there such a disease as fish poisoning? I live in a town in which there is a fishing industry consisting of catching cutting and packing fish. During our fishing season many patients give the following history: I have been cutting fish and stuck a fish fin in my hand and for the last day or so it hurts so badly I can't work. Examination reveals an area of erythema varying in size from 2 to 4 cm in diameter, quite painful, and the joint nearest the injury is often swollen and painful. What would you suggest for treating these cases? Many here use white lead. I have been using potassium permanganate 1:1000 as a wet dressing. This seems to give better results. After it has been used a few days the erythematous area sheds off. The joint pain responds slowly to the use of salicylates.

C S CREDLE M D, Colerain N C

ANSWER—The disorder in these fish handlers is most probably erysipelas, also known as erythema serpens or erythema migrans. It occurs in persons whose occupations bring them in contact with animal carcasses or their products—pelts, bone, manure. In this country it is most common along the Eastern coast, most of the reported cases occurring in fishermen from the vicinity of the Chesapeake Bay coast. Gilchrist found that bites from crabs most often preceded the disorder. Rosenbach, who gave the disease its name, recovered an organism of the order of cladothrix from the lesions and also succeeded in reproducing the malady by inoculation experiments. At the present time the belief is increasing that this is the same organism that produces swine erysipelas.

The disease commences about two days after trauma in handling fish, crabs or animal products, with a livid red, sharply defined, edematous spot on the fingers or hand. The lesion spreads at the edges and clears in the center, to become circumscribed. Several lesions may form simultaneously or in succession with the production of scalloped figures. Itching, burning and pain are the usual subjective symptoms. General symptoms are usually lacking. The disease runs its course in from two

to four weeks without sequelae. The reports do not state whether there is permanent immunity. This is the mild form of the disease. In addition to this, more severe and serious forms include the production of lymphangitis with fever, malaise and headache, a chronic form with arthritic symptoms, and one with signs of sepsis, endocarditis and arthritis.

Local applications of warm antiseptic wet dressings have been employed with benefit. Potassium permanganate, resorcinol and ichthammol can be used in this manner. The latter in a 40 per cent strength in petrolatum is highly recommended. Gilchrist applied a 25 per cent salicylic acid plaster. Specific horse serum prepared for use against swine erysipelas has given prompt improvement. The injections may be made intramuscularly or around the lesions. Ultraviolet irradiation may be useful.

The disease in fishermen represents an industrial problem which is partially met by the recent use of specific serums. In veterinarians who accidentally inoculate themselves with the organisms and who may thus acquire the serious forms of the disease, it represents more than a mild hazard.

ATROPHIC ARTHRITIS

To the Editor—A white man aged 41 has nonvenereal atrophic arthritis in his feet, knees and hand. He has had the condition for three and one-half years. He has been able to get about on crutches about one-fourth of the time. He does not suffer much pain after the first five or six days following an attack but has a weakness and a continuous soreness in the joints and is unable to walk or use his limbs. He had his tonsils removed in July 1934. Most of his teeth have been taken out, the remainder have been roentgenographed twice and have been pronounced perfectly sound by every technician and dentist. I have been unable to detect any other symptoms. He was in the Army and Navy Hospital at Hot Springs Ark., four and one-half months where practically the same diagnosis was made that I have given. Previous treatment was with sodium salicylate by mouth and intravenously. cinchophen, all preparations of a sodium salicylate base and nonspecific protein therapy, chaulmoogra oil, lactogen, typhoid vaccine intramuscularly and intravenously, hydropobia serum intramuscularly, and many other preparations of the same nature. If you know of any preparations or method of treatment that you can recommend please notify me at once for the benefit of the patient. Please omit name.

M D Illinois

ANSWER—It is assumed that all areas of focal infection have been examined and that there is no infection in the sinuses or prostate. The patient's weight is not mentioned. The majority of patients with atrophic arthritis lose weight. If the patient is not still overweight, a rather high vitamin, high caloric, anticonstipation diet would seem advisable. The use of physical therapy is not mentioned. It was undoubtedly given while the patient was in the hospital, but it is important for most patients with atrophic arthritis to continue some form of physical therapy daily over long periods. This can best be done by a program of home physical therapy carried out daily by means of the efforts of the patient and his family, supplemented by professional physical therapy two or three times a week, or oftener if necessary. If possible, some form of occupational therapy should be instituted under the supervision of the attending physician to prevent or correct deformities and to strengthen affected muscles. It is stated that the patient is on crutches about one-fourth of the time, and it is assumed that he is bedfast the rest of the time. This would suggest that deformities already exist and that orthopedic corrections may be necessary. At any rate, orthopedic consultation is indicated to prevent impending deformities. It is the common habit for bedfast patients with arthritis to lie in bed with pillows under their knees. This fosters flexion deformities and the habit should be prevented. Even if the patient is bedfast, certain daily exercises in bed should be instituted. Recently a summary of methods of treatment to correct and prevent deformities appeared. Hench, P S, and Meyerding, H W. The Results of Failure or Neglect in the Care of Chronic Infectious (Atrophic) Arthritis. Characteristic Deformities and Their Prevention, *M Clin North America* 18:549 (Sept.) 1934.

Many medicines have been given. Unfortunately, medicines seem of little value in this disease except as analgesics. Since foreign protein and nonspecific vaccines and serums have already been given without relief, a trial of one of several vaccines made from so-called arthrotropic streptococci is suggested. The vaccine should be given for at least three to six months. However, there is no one vaccine available that is consistently helpful. Other methods in current favor which seem helpful to some patients include x-ray therapy. Injections of gold or sulfur, the use of concentrated viosterol and other methods are now being used but their exact value has not been determined. For a current opinion of the value of these and other procedures in atrophic arthritis the correspondent is referred to an exhaustive review on the subject by Hench, P S, Bauer, Walter

Fletcher, A. A., Ghrist, David, Hall, Francis, and White, T. P. The Problem of Rheumatism and Arthritis. Review of American and English Literature for 1935 (Third Rheumatism Review), *Ann Int Med* 10 754 (Dec) 1936

EXFOLIATIVE DERMATITIS AND PSORIASIS

To the Editor—What is the cause and treatment of persistent redness, scaling and itching of the whole body of a woman aged 88 who has suffered from psoriasis and who had apparently shown complete disappearance of the psoriasis patches several months ago? She is now using a hydrous wool fat and olive oil mixture containing 1 per cent phenol and 0.5 per cent menthol with partial alleviation of the symptoms. She is receiving treatment with 2 mg daily of arginin for her heart which had shown signs of failure several months previously evidenced by a pulse of 100 and edema of the extremities. She also takes A, B and D vitamins daily. Owing to her prolonged confinement in bed there is a marked atrophy in the muscles of the legs and thighs so that it is impossible for her to stand without support. She is bedridden most of the time. Her appetite is very good. The heart rate is 84 per minute. Is the condition a form of muscular atrophy? Too frequent massaging of the muscles causes fatigue. She received large amounts of amino-acetic acid until a month ago when it was discontinued because no improvement was shown in the condition of the muscles. What is the diagnosis and treatment? Please omit name. M. D. Connecticut

Answer—The patient apparently has generalized exfoliative dermatitis, secondary to psoriasis. Goeckerman and O'Leary (*The Journal*, Dec 17, 1932, p. 2102) reviewed twenty-two such cases, giving them the title of erythroderma psoriaticum, a term used to designate the generalization of psoriasis vulgaris to a point at which the usual clinical characteristics have disappeared and have been replaced by those of exfoliative dermatitis. This article should be read, because it gives factual data and pertinent discussions by several dermatologists. In short, the condition occurred in about 1 per cent of all cases of psoriasis observed by the authors, in people of various nationalities, in old and young, some with arthritis, and they were of varying durations. The use of arsenic internally and irritating drugs locally seemed to precipitate most of the cases, in others no etiologic factors were found. Associated cardiac, renal or other diseases were present in some of the patients, but there seemed to be no important etiologic relationships between them. In differentiating the conditions from other forms of exfoliative dermatitis, histologic study of a biopsy section is of value. In an occasional case recovery was spontaneous, but in most cases when there was no treatment the tendency was for them to persist, sometimes for years. Goeckerman and O'Leary achieved their best results with the use of their coal tar and ultraviolet ray regimen. At night an ointment of 3 per cent crude coal tar is applied to the skin. In the morning it is wiped off and the entire body is then exposed to ultraviolet radiation. The treatment is administered as often as is feasible daily if possible. With this regimen some cases cleared up and the patients remained well for considerable periods, others recurred after a short time.

EPISIOTOMY

To the Editor—Will you please answer the question as to the best method to perform an episiotomy. I am not unmindful that some recent teachers and authors advocate a mediolateral incision either right or left or both and if these are correct when is it proper to do the right and when is it proper to do the left? Is it not a fact that some famous obstetricians advocate the median incision down to the sphincter ani? Any information along this line will be greatly appreciated.

E. R. GOONLOE, M.D., Paducah, Ky.

Answer—Opinions differ as to the best method of performing an episiotomy. Lateral episiotomy has practically been abandoned in favor of the median or the mediolateral. Bilateral episiotomy of the latter type is seldom if ever necessary.

The indications for any episiotomy are of two main types: 1. Fetal (a) where there are definite signs of fetal distress, (b) where a rigid perineum may endanger the fetus by causing an unduly prolonged second stage. These indications apply only when the perineum is interfering with the progress of labor. 2. Maternal (a) where tears are probable, as in most primiparas, (b) where the last part of the second stage of an otherwise natural labor may be facilitated, (c) where operative delivery from below is indicated, such as in breech extraction, version or forceps, and the perineal structures are not sufficiently relaxed to permit delivery without damage to the soft tissues.

There are certain advantages and disadvantages to both the median and the mediolateral episiotomy. They are both simpler to repair than the common, irregular tears, but the median is easier than the mediolateral. Both have the disadvantage of possible extension upward into the vaginal wall and downward

or backward into the environmental structures. The median is more apt to extend into the sphincter ani and rectum, and the mediolateral into the ischioanal fossa. The main question to decide is the amount of room required for delivery of the fetus without risking a serious extension of the incision. A wide perineum favors a median episiotomy while a short one indicates a mediolateral episiotomy. It should be clearly understood that a median episiotomy is not applicable to all cases in which an episiotomy is indicated. The mediolateral form may be employed in any or all cases in which an episiotomy is necessary, and it makes no difference whether the incision is made on the right or the left side.

The occasional operator should accustom himself to the performance and repair of only one type, as he can thus acquire better judgment as to the depth of the incision and the technique of repair.

HIVES AFTER DYE TEST FOR GALLSTONES

To the Editor—I underwent an operation for left inguinal hernia Oct. 26, 1936 and was given spinal anesthesia because I wished to avoid coughing and sneezing after the operation. For the past eight years I am now 46 I have suffered from hay fever (fall type ragweed) and occasional flare ups of an old ethmoid sinusitis. Therefore I postponed the operation to avoid the sneezing. That was fine as I never sneezed once. However having had several attacks of epigastric pain and vomiting following overindulgence in rich (fatty) food requiring morphine I decided to have a cholecystogram just prior to my departure from the hospital. Accordingly I took a dose of shadocol after dinner (1 30 p.m.) and at 5 o'clock I developed hives and after a light supper I took another dose of shadocol (two dose technique). Then I was given three doses of epinephrine 3 5 and 5 minims (0.18, 0.3 and 0.3 cc) at 6 45 p.m., 8 and 9 45 p.m. At 10 15 I went into shock, which lasted four hours, and was given caffeine with sodium benzoate and later pantopon (a mixture of opium and alkaloids) hypodermically. The next morning roentgenograms were taken and the results were not conclusive for gallstones. What I want to know is: What gave me shock shadocol or epinephrine? The people who make shadocol said it never did that to anyone so far as they knew. I know that epinephrine can cause shock but I received only 13 minims (0.8 cc) in all. I also know I am allergic (viz. hay fever and hives from shadocol). Another fact that might help is that for two years my basal metabolism has been low and I take 1 grain (0.065 Gm.) of thyroid daily to keep it around normal. Would the spinal anesthesia cause the backache which I have had since leaving the hospital? At present I am engaged in active general practice and work all day but am bothered with a backache which seems to have started after the operation. Please omit name.

M. D. Pennsylvania

Answer—Following the intravenous injection of dye for gallbladder visualization the occurrence of hives is not infrequent, but we do not know of any instance of shock.

Epinephrine produces an immediate rise in blood pressure followed by a fall, which is frequently lower than the original level. The symptoms complained of developed within thirty minutes after the last injection of epinephrine, and since individuals may react to a different degree under different conditions this was probably responsible.

Backache after an operation is a common complaint. It varies with the hardness of the table, the position of the patient, the presence and extent of vertebral arthritis, the amount of individual curvature and the degree of muscular relaxation obtained by the anesthetic, all of which affect the flattening of the lumbar curves with a tendency to strain with subsequent soreness and often long persisting backache.

One of the best preventives is the use on the operating table of a thick but soft mattress, preferably with an air cushion.

DEATH RATES FROM ARTERIOSCLEROSIS AND HEART DISEASE

To the Editor—What do statistics show if any are available, regarding the increase in death rate and morbidity as a result of arteriosclerosis, high blood pressure and apoplexy during the past ten years? Please omit name.

M. D. Texas

Answer—In a study by Rollo H. Britton, senior statistician of the United States Public Health Service (*Pub Health Rep* 51 947 [July 17] 1936) the upward trend in the mortality rate for heart disease was shown to be increasing at the rate of 35 per cent a year over a seven year period, the study being based on two periods from 1920 to 1926 and from 1927 to 1933. No available data are known to me which adequately cover the changes in morbidity from heart disease during the period under discussion.

There are two facts which make the interpretation of statistics concerning morbidity and mortality as a result of arteriosclerosis, high blood pressure and apoplexy difficult. First, the greater precision in diagnosis obtaining at present is reflected in all mortality statistics by an apparent increase in certain forms of heart disease, some of which are frequent complications

of the entities asked about. For example, coronary occlusion is a common diagnosis today, whereas twenty years ago it was very rare. Some authors believe that this change in nomenclature is the major factor in the apparent increase mentioned, but the consensus is that the increase is real. Second, the decrease in morbidity and mortality in nearly all the infectious diseases (except pneumonia and influenza) which has resulted in such a striking increase in life expectancy in the past few decades results in a larger number of the population reaching the age at which degenerative disease is to be expected.

This raises the question as to whether the increase in heart disease is a relative or absolute increase and this is a difficult question to answer. Some students of the problem believe that the apparent higher incidence of hypertension and angina pectoris among city dwellers as opposed to the rural population and especially among business and professional men indicates that environment plays a part in the etiology. Opposed to this is the high incidence of hypertension among Negroes.

UNCERTAIN CAUSE OF DEATH

To the Editor—Please help to clear up the etiology in this case. A woman, aged 64, 5 feet 6 inches (168 cm.) in height, married, whose father, mother, brother and sister died over 60 of apoplexy or Bright's disease has a good previous history except for syphilis twenty years ago (treated since then with arsphenamine and mercury with a negative Wassermann reaction since) arthritic pains in the left shoulder and knee never confining off and on for five years, frequent intense headaches for twenty-five years, salicylates and barbiturates being used and some carious teeth. The patient has had regular dental care but six months ago the left molar was broken in extraction and the roots were left in situ on the dentist's assurance that the gum would heal over it (and it did). Her last sickness was preceded by two attacks of sternal pains of considerable intensity followed after one week by complaints of great weakness and pain in the left shoulder and left knee. Onset was sudden. Chills, pains a temperature between 103 and 104 F., constipation and aberration a tense abdomen, scanty, 4 plus albuminous urine and a deepening stupor. The Wassermann reaction was negative. The lungs were normal. X-ray examination showed the heart somewhat enlarged. Death occurred at the end of eight days. Here was a toxic condition. How was it brought about? What role could the carious tooth, the arthritis, the past syphilis play? Please omit name. M D, Louisiana.

ANSWER—The chills and fever indicate that the fatal illness was an infection or was associated with infection. The tense abdomen suggests peritonitis. The infection may have been primary or secondary to some existing focus, as in a joint or the throat. The enlargement of the heart may have been due to valvular or myocardial lesions, if due to myocardial lesions, the possibility of syphilis being at the bottom cannot be excluded. The question arises whether the "two attacks of sternal pains of considerable intensity" were manifestations of angina pectoris.

USE OF EDELMANN-GALTON WHISTLE

To the Editor—I am wondering if you can tell me exactly how to use the Edelmann-Galton whistle 2106 which I now have in my possession together with other equipment which I bought from the estate of a recently deceased doctor. Please omit name. M D, Maryland.

ANSWER—Each Edelmann-Galton whistle is supposed to be supplied with a table showing which pitches are produced when the whistle is set at certain points. If the correspondent will write to T. H. Edelmann of Munich, giving the number of the whistle, we believe that a complete table will be furnished. It would be advisable to request the manufacturer also to send a brochure, if one is available, giving detailed instructions regarding the use of the whistle.

The distal portion of the whistle is known as the pipe length (pfeifenlange), and the proximal portion to which the rubber tubing and bulb are attached is known as the aperture width (maulweite). When the table for the particular whistle is at hand, it will be noted when the pipe length is set at a certain point by turning the attachment, and the width of the aperture is set at a certain point, which tone is produced. The great difficulty with these whistles is that at the highest pitches they require an enormous pressure of air in order to produce a definite tone and not a mere blowing sound. But even at the lower pitches it is often difficult for patients to distinguish between the hearing of a tone and the mere blowing sound of the air. It is necessary to avoid contact with the sharp edges of the apertures in order that the pitch may not be altered and the quality changed.

In testing the patient, hold the whistle parallel with the ear at a distance of 8 or 10 inches, and then with even pressure compress the bulb and test the patient first with the highest tones, gradually descending until the point is reached at which the tone and not the blowing sound is distinguished. This will give the high tone limit for that particular individual.

SLOWNESS AND STUTTERING IN CHILDREN

To the Editor—I have a granddaughter 12 years of age a strong healthy active, energetic child who has never had any serious illness. She has always stuttered. We sent her to Professor Muijskens of the University of Michigan a year ago who said she was hardly old enough to profit much by special training but that he thought she would be in a year or two. So we expect to send her to one of his summer classes next year. For the last two or three years, or perhaps longer she has gotten into a habit of being slow dilatory and procrastinating. She is late at meals and eats slowly. I have seen her stay an hour at the dinner table. She is slow on going to bed. If the hour for retiring is 8:30 she may not get into bed until 8:45 or 9. She dresses in the morning as slowly as she undresses at night and will get down to breakfast from ten to thirty minutes late. What would you do with such a child especially as regards the latter state? Where can I find any reading matter on the subject? To whom can I write for information about her? Any help you can suggest will be gratefully received. M D Michigan.

ANSWER—To know what to do with such a child involves determining, if possible, the causes for slowness. If physical factors such as endocrinologic disturbance can be ruled out the problem should be regarded as one of habit training. Some children who stutter are sluggish in motor activities, apparently on the basis of rather poor general muscular coordination. This should be evaluated for this child. Usually such slowness occurs in children on whom no systematic demands for conformity to routine are made. A child will not remain at the table for an hour if food is not permitted to remain on the table for an hour. If there are consequences resulting from dilatory habits about getting up and going to bed, such as some reasonable deprivation of something desired or agreeable, the child will soon enough learn that it pays to stick to the required routine.

Usually the parents' methods of dealing with the child are at fault.

See "For Stutterers" by Smiley Blanton and Margaret Gray Blanton, D. Appleton-Century Company, New York, 1936. Write to the Children's Center, 3743 Brush Street, Detroit, or to the Institute for Psychoanalysis, 43 East Ohio Street, Chicago.

TRAUMA AND CARDIAC INJURY

To the Editor—A man aged 62 without cardiovascular symptoms and apparently in good health slips and falls striking the cardiac area of the anterior part of the chest on a heavy iron ball. He is able to get up and be about for the following twenty-four hours but marked cardiac decompensation develops during the next twenty-four hours. Is such a trauma a valid cause for cardiac failure? If the patient is employed would this be a compensation injury? Can you cite literature which covers such indirect trauma to the heart? M D New York.

ANSWER—Yes, it is reasonable to assume here that the trauma was responsible for the cardiac injury. Myocardial contusion or possible rupture of muscle or valve might have resulted from this injury whether or not there was any underlying heart disease, although of course underlying heart disease if it existed would have favored heart damage from the blow. Physical examination before and after the injury and electrocardiograms taken after the injury would be of great value in the analysis of the case. Contusion of the heart muscle or other trauma may give rise to electrocardiographic changes that may resemble myocardial infarction. For the literature, consult the chapter on Trauma and the Heart by Drs. Paul D. White and R. Earle Glendy in the new book on Trauma and Disease, edited by Dr. Leopold Brahdly.

PARALYSIS AFTER ANTITOXIN

To the Editor—There is a child now in high school who has a paralyzed arm which followed use of diphtheria toxin antitoxin given for active immunization about eight years ago. Paralysis appeared a few weeks after the giving of the preparation and its use is blamed for the paralyzed arm. Is there any evidence or literature on the use of toxin antitoxin or any of the toxoid preparations causing paralysis? I realize that it may well be due to other causes in any certain case but I am especially interested in knowing if there are any authentic or probable cases in which the toxin antitoxin or toxoid could have caused a paralysis. Please omit name. M D Wisconsin.

ANSWER—The paralysis in this case is most likely unrelated to the injection of diphtheria toxin-antitoxin. Usually, diphtheria toxin causes a slowly appearing general paresis beginning with palatal paralysis, and sometimes by loss of function of the muscles of the eye, and lasts from two to six months. The development of paralysis following diphtheria toxin antitoxin and diphtheria toxoid is rare. Papadato (*Arch de med d enf* 37:37 [Jan] 1934) reports the case of a girl aged 8 years who the day following a single inoculation of diphtheria toxin-antitoxin developed acute optic neuritis, mild paresis of the right facial nerve, and muscular twitchings about the mouth.

all of which completely subsided in two months. A second case is reported by Schirppa (*Prat pediat* 12 531, 1934) in a boy aged 6 years who immediately after the second injection of diphtheria toxoid developed paralysis of the soft palate with accompanying regurgitation of food and nasal voice, fever, hypotonia of the muscles of the lower extremities, mild ataxia and absent, and diminished patellar reflexes. Perfect recovery occurred in one month. No cases of permanent paralysis have been described.

RECURRENT DISLOCATION OF SHOULDER

To the Editor—I have a patient who has a recurrent dislocation of her shoulder. She has been advised to have an operation by an orthopedic surgeon to correct the condition. He states that he has had practically no failures from this type of operation. Could you refer me to a source where I can obtain accurate and impartial information with regard to this operation whether the failures are as negligible as indicated by this orthopedic surgeon and whether there is much scarring following the operation? The patient is a young woman and she would strenuously object to a prominent scar.

M D Iowa

ANSWER—Operation for recurrent dislocation of the shoulder has reached a high stage of efficiency, especially since the event of the Nicoli operation. In this operation the tendon of the long head of the biceps transects the upper end of the humerus, acting somewhat on the order of the ligamentum teres of the hip. There is a scar from $2\frac{1}{2}$ to 3 inches long over the antero-lateral aspect of the shoulder joint. This is unavoidable, but it can be placed in such a position as to minimize its prominence.

Satisfactory results were obtained in approximately 90 to 95 per cent of the cases in which the operation was performed.

NECESSITY FOR EFFECTIVE FLUE IN BUTANE GAS STOVES

To the Editor—The public school building at this place has recently been equipped with heating stoves which burn butane gas. There is no provision made for the removal from the room, of the products of combustion. Some children complain about an uncomfortable feeling in the head. Many have colds. I am not an engineering expert but I do know that this form of heating a room is not conducive to health. If you can support my contention with the trustees that some provision should be made for the removal of the products of combustion (carbon dioxide and probably some carbon monoxide) from the room, you will confer a favor on me and I am sure a blessing to the occupants of the room if you will write me a letter explaining the conditions. I will show your letter to the trustees. This butane gas is said to produce a more intense heat than does ordinary natural gas.

M D Texas

ANSWER—In the light of the limited factual information concerning the installation and the operating conditions of the heating stoves referred to, only a generalized comment can be made. The recommendations of authorities with regard to flue connections are that any gas appliance (burning butane or other gases) used for domestic purposes having a demand in excess of 50,000 British thermal units per hour should be connected to an effective flue. Several appliances installed in the same room and having an aggregate demand at normal rating as great as 30 British thermal units per hour per cubic foot of room content should be connected to an effective flue.

SENSITIVITY TO PODOPHYLLUM?

To the Editor—I have recently seen a case in which rather severe ulcerative gingivitis occurred following the administration of some capsules containing unknown drugs. No other cause could be made out for this condition. The blood pictures were normal. Smears and cultures were essentially negative. A dentist who saw the patient states that he has seen several cases of this kind, one of the patients happening to be his wife. He had the capsules used by his wife analyzed and found that they contained podophyllum. They were prescribed by the same physician in all these cases. Have you any record of a sensitivity to this drug?

S B FORBES M D Tampa Fla

ANSWER—There seems to be no record of cases of gingivitis due to podophyllum even in complete and exhaustive compendiums of drugs and their ill effects. In the complete bibliographic file of E. William Abramowitz, the only case recorded of ill effects due to podophyllum is one of keratitis and dermatitis produced by dust of the root of podophyllum, reported by Hutchinson in the *Medical Times and Gazette* 2 516, 1872. M. Peshkin has reported that podophyllum may cause asthma.

As podophyllum and the other resinous cathartics are practically unknown as causes of dermatitis, stomatitis or gingivitis, it seems more likely that some other cause produced the cases of gingivitis in question. This other cause may well have been some other medicament contained in the suspected capsules. A list of drugs likely to cause mucous membrane lesions may be found in Prinz and Greenbaum's "Diseases of the Mouth

and Their Treatment" (Philadelphia, Lea & Febiger, 1935) and in the chapter on Drug Eruptions, by Ferdinand Zinsser in Josef Jadassohn's *Handbuch der Haut- und Geschlechtskrankheiten*, volume 14, No. 1.

PNEUMONIA IN AGED

To the Editor—A woman aged 88 was in apparent good health until yesterday noon when she was suddenly seized with a chill fever and began to expectorate prune juice sputum. I was called in the evening and made a diagnosis of lobar pneumonia of the left upper lobe. The temperature was 102.2 F by mouth, the pulse 74 and respiration rate 18. There were diminished resonance and diminished breath sounds over the left upper lobe with crepitant rales present. Tonight her temperature was 101, pulse 74 and respiration rate 18. The left upper lobe was completely consolidated and egophony was present. Can you explain the reason for the normal respiration and normal heart action? This is the first time I have seen such a paradox in lobar pneumonia. Please omit name.

M D, Iowa

ANSWER—It is highly probable that the absolutely identical pulse and respiration rates were merely fortuitous. Such identical observations are uncommon in normal persons.

It is possible, but unlikely, that the pulse rate might be fixed by an abnormal cardiac rhythm. An auricular flutter or a complete auriculoventricular dissociation might produce such a fixation of the heart rate, but a rate of 74 would be unusual in either of these conditions. There is nothing, however, to produce such a fixation in the respiratory rate.

Pneumonia in the aged shows many bizarre features. It is not infrequently afebrile, less often it is associated with a pulse rate that does not exceed normal limits, and still less often the respiratory rate is relatively low. An absence of the usual leukocytosis is another departure from normal. These aberrations are thought to be due to the inability of the patient to respond in the usual manner to stimuli. They are usually looked on as bad prognostic signs but not necessarily hopeless ones.

Lobar pneumonia at 88 is of rather infrequent occurrence and there is not too much evidence concerning it.

PARESTHESIA OF FACE

To the Editor—A man aged 52 has for the past year and a half been troubled with a paresthesia of the left side of the face described as a numbness and leathery feel to the skin. It first started on the left upper lip as a tingling often making the motion of brushing off a fly, it spread to the cheek, the nose and the forehead. Now it is beginning in the left part of the lower lip. There is no pain. Neurologically there is no abnormality other than loss of taste on the left half of the tongue. Pain pressure and temperature perceptions are intact. There is no motor involvement. The teeth are all vital with no evidence of infection. The tonsils have been removed. The left antrum is cloudy. Is there any hope for relief or prevention of progress of the condition? Please omit name.

M D, Wisconsin

ANSWER—The lesion, a spreading one is causing dysfunction of the second and third branches of the trigeminal nerve on the left side or of the gasserian ganglion. The possibility of infection is suggested by the condition of the left antrum and this should receive attention. In a man of 52 however, with progressive disease of this type, pressure from tumor or aneurysm must be strongly considered. The lack of pain is against a primary tumor of the gasserian ganglion, but tumors of neighboring structures or aneurysm of the internal carotid artery would give the symptoms described. The involvement of taste, supplied by the lingual nerve, occasionally occurs in lesions as high as the ganglion or its primary roots, although most of the taste fibers pass to the brain along with the facial nerve. Neurosyphilis should be ruled out by an examination of the spinal fluid. Even if the fluid is negative for syphilis, valuable information might be obtained with regard to abnormal pressure or increased total protein content. If operation is to be considered, the advice of a neurosurgeon is to be recommended.

GROUP SKIN TESTS FOR ALLERGY

To the Editor—I should like to have an allergist's opinion on the comparative practical accuracy of the diagnostic use of group proteins for skin tests. The method permits covering a larger field so much more quickly and inexpensively that I should like to employ it if it is accurate.

M D Massachusetts

ANSWER—Most allergists agree that the use of group skin tests is to be avoided. The objectionable feature in this method is the dilution of the individual antigen in the mixture. This is of special importance in the intracutaneous type of testing. If a positive reaction is obtained from group tests, it then becomes necessary to test for the individual allergens contained in that group.

Council on Medical Education and Hospitals

ABSTRACT OF MINUTES OF MEETINGS HELD BY COUNCIL ON MEDICAL EDUCATION AND HOSPITALS, ATLANTIC CITY, JUNE 6 AND 9

The following action was taken with regard to the Schools of Medicine of the Universities of North Dakota and South Dakota

It was voted that the same recognition be extended to the classes entering this fall that has been given to the students who were regularly enrolled during the past academic year

The School of Medicine of West Virginia University was restored to the Council's approved list as a School of the Basic Medical Sciences, such approval applying to the courses in anatomy, physiology, biochemistry, bacteriology, pharmacology and pathology

It was voted to place Meharry Medical College on probation

It was voted to restore the University of Georgia School of Medicine to the Council's approved list of medical schools

It was voted that the Council again express appreciation of the services rendered by Dr Herman G Weiskotten and Rev Alphonse M Schwitalla in connection with the medical school survey and invite their further cooperation in the preparation of a final report

Who Gave the World Syphilis? The Haitian Myth By Richmond C Holcomb MD FACS With Introduction by C S Butler AB MD LL.D Rear Admiral Medical Corps U S Navy Cloth Price \$3 Pp 189 New York Froben Press 1937

Admiral C S Butler has for years, certainly since he was Captain Butler been preaching in all seasons that syphilis was not of American origin It is not too much to say that he is an evangelist who can see only obstinacy and a pretty high degree of stupidity in all those who hold so absurd a view as that syphilis did not exist in Europe before the return of Columbus on his first American voyage

Captain Holcomb belongs to Admiral Butler's school The temperance of his attitude on the subject is shown by his labeling the book at the very outset with the title 'The Haitian Myth' His cold scientific consideration of the subject begins with a poem A Vision of the Search for Truth As poetry is usually assumed to be an expression of the emotions, this beginning might be interpreted as evidence of a fairly emotional consideration of his subject, and the interpretation would turn out to be correct

The whole book is devoted to a consideration of the documentary evidence in the case, especially a devastating examination of the historical evidence, meaning by historical that from written history The work gives a hostile summary of the criticisms to be made against the early documentary evidence for the American origin of syphilis, but it is the sort of summary of the evidence that gets the reader nowhere Some men think the early documentary evidence for the American origin of syphilis is very strong, Captain Holcomb and Admiral Butler seem to think that those who come to that conclusion from an examination of the evidence are proper subjects for an *inquere de lunatico* It is like interpretations of Hamlet's soliloquy different interpreters read into it different meanings—usually what they like, you pay your money and you take your choice The subject of the origin of syphilis will never be conclusively settled in that way If it is ever settled it will be on examination of bones Syphilis leaves indubitable evidence in bones There is unquestionable evidence in pre-Columbian bones in this country Virchow in 1896 said that there were no known syphilitic bones of pre-Columbian age in the museums of Europe Elliott Smith in 1930, as the result of an examination of about 30,000 bodies of ancient Egyptians and Nubians, stated that no traces of syphilitic injuries to bones or teeth have been found among them Herbert U Williams who has thoroughly studied the subject, stated in 1932 that he has not been able to find any unquestionable syphilis in European bones of pre-Columbian age but that there is almost an embarrassment of riches of syphilis in pre-Columbian American bones This is stubborn evidence from impressive authorities Much more of the same sort could be produced If somebody would produce a single bone of unmistakable pre-Columbian age and of unmistakable European origin, in the opinion of unprejudiced authorities, such as those listed, it would settle the question Let the proponents of the Haitian Myth tackle that problem Captain Holcomb does not even take it up in his book

Consulti medici Di Giambattista Morgagni Pubblicati da minute inedite a cura di Enrico Benassi Classici italiani della medicina II Boards Price 120 lire Pp 380 Bologna L. Cappelli 1935

Morgagni's fame rests on his *De sedibus morborum* (1761) which, as Virchow said, entitles him to be called the father of pathologic anatomy Morgagni, who died in 1771, left a large number of manuscript notes to his pupil Michele Girardi Though Girardi lived until 1797, he never edited or published these papers Through the duke of Parma the manuscripts were acquired from Girardi's heirs and deposited in the Palatine library, where the twelve volumes have long been carefully guarded as precious almost sacred treasures They now appear, published in attractive quarto form, under the auspices of the city of Forlì, Morgagni's birthplace, ably edited by Enrico Benassi They are reminiscent of the *De sedibus*, being the notes on a hundred cases selected by Morgagni from files that date back to the days of his youth Diseases of nearly

every description are discussed—of the stomach, bowel, heart, bone, pelvic organs and nervous system Aneurysms are taken up, menstrual troubles and psychic disturbances Clinical facts are concisely stated, diagnoses are skilfully worked out, advice is given to the patient or to the physician who referred the patient Benassi, whose task of deciphering and editing has been one of difficulty, has analyzed these papers in a critical manner His comments on Morgagni as revealed by these consulti are well worth reading The master here writes in Italian with a style that, as Benassi says, is charming as to form, precise as to its use of terms, harmonious in its proportion All this, combined with his logical reasoning, makes the treatment of the subject almost perfect, as the editor enthusiastically terms it That errors in diagnosis are evident to the reader of today, who interprets with the aid of auscultation, bacteriology, instruments and laboratory methods and with the wealth of medical knowledge acquired since 1771, need excite no surprise Yet one marvels at the scientific method employed and at the accuracy of the results obtained An interesting feature of the volume is its revelation of Morgagni not alone as the scientist but as the practitioner and consultant, careful not to offend or unjustly to criticize his colleague, simple yet explicit in giving advice to both patient and family doctor As the editor points out, Morgagni, while using more drugs than physicians do today, and some of them astonishing in their character, was really ahead of his time in his moderate and simple treatment He stressed diet, fresh air and climate and was comparatively conservative in his use of mercury, bleedings and drastic purgatives The work is an important contribution from the standpoint of medical history The Italians are to be thanked for permitting others to share their pardonable pride in the accomplishments of one whose handwritten notes of any kind have an interest not only for Italy but for the entire medical world; for Morgagni was of world stature

The Colon as a Health Regulator—From a Surgeon's Point of View The Effects and Treatment of its Developmental Abnormalities By Sir Henry M W Gray KBE CB CMG Consultant in Special Military Surgery (Orthopaedic) Home Service Montreal Cloth Price \$2.50 Pp 100 with 31 illustrations Toronto Macmillan Company of Canada Limited 1936

Here is a theory that we have all heard before, namely, that one can make over a half crazy, constitutionally inadequate and sickly person either by dividing adhesions around the colon when they can be found or else by making a large bunch of traumatic adhesions when congenital ones happen to be absent Sir Henry Gray's poor opinion of the critical faculties of the medical profession is to be found rather frankly expressed in his statement to the effect that 'less privileged members of the profession may be tempted to cast the book aside as being another fantastic result of a gospel preached by Sir William Arbuthnot Lane, which was at first ridiculed by many theorists whose chief stimulus to a thoughtless opposition was supplied apparently by jealousy of his personal success' Apparently Sir Henry was spared somehow from contact with the procession of miserable human wrecks which, fifteen or twenty years ago, went about from clinic to clinic hoping against hope that some one could put them back again to where they were before some surgeon had attempted to duplicate on them the results claimed by Sir Arbuthnot Some of these poor people had to be operated on again and again in an effort to straighten out the mess that had been made by the misguided meddling with the colon One of the saddest features about so much of this operating was that in most cases the patient was a poor nervous wreck to begin with, some one on whom no surgeon of good judgment would ever have wanted to operate One cannot help wondering every so often how it comes about that some men can claim such marvelous results from an operation or a type of treatment which in the hands of others brings either disaster or lack of any improvement Perhaps some of these optimists are like a certain choleric and forceful clinician who, whenever a woman returned to his office, after having taken his treatment would fix her with a stern and glittering eye and say 'You're better, now don't you deny it' Needless to say it was a rare person who dared talk back, and as a result the clinician walked in the happy feeling that he cured all his patients

The Dispensatory of the United States of America By Horatio C. Wood Jr. M.D. Ph.M. Professor of Pharmacology and Therapeutics in the University of Pennsylvania. Charles H. LaWall Ph.M., D.Sc. Ph.D. Professor of Pharmacy in the Philadelphia College of Pharmacy and Science. Heber W. Youngken Ph.M. Ph.D. Professor of Botany Pharmacognosy and Materia Medica in the Massachusetts College of Pharmacy. Arthur Osol Ph.G. M.S. Ph.D. Associate Professor in Physical Chemistry and Director of the Chemical Laboratory in the Philadelphia College of Pharmacy and Science. Ivor Griffith Ph.M. Professor of Theory and Practice of Pharmacy in the Philadelphia College of Pharmacy and Science. and Louis Gershenfeld Ph.D. B.Sc. Ph.M. Professor of Bacteriology and Hygiene in the Philadelphia College of Pharmacy and Science. Centennial (22d) edition thoroughly revised largely rewritten and based upon the eleventh revision of the United States Pharmacopoeia National Formulary Sixth Edition and the British Pharmacopoeia 1932. Cloth Price \$15 Pp 1894 Philadelphia & London J. B. Lippincott Company 1937

A centennial edition of any book is noteworthy. Surely a book has proved its value when its age mounts to the hundred year mark and it has passed through twenty-one editions. For this, the twenty-second edition, congratulations are extended to the editors and contributing editors who have amassed the informative material in more than 1,800 large pages. The book is divided into three parts. The first part contains the discussion of drugs in the new U. S. Pharmacopoeia, the National Formulary and the British Pharmacopoeia. The second part records a large number of chemicals and unofficial drugs, many of the latter being taken from New and Nonofficial Remedies. Included in this part is a summary of a number of diagnostic tests and an excellent article on hydrogen ion concentration. The third part contains the general tests and standards of the U. S. Pharmacopoeia, as well as a collection of reagents used in urine and blood chemistry. The vast amount of information will be most valuable to pharmacists, but the book is a compendium of information that physicians, biologists, pharmacologists and many others should not overlook.

Le chirurgien devant l'état puerpéral Grossesse accouchement suites de couches. Par Marcel Metzger professeur agrégé à la Faculté de médecine de Paris. Préface du Professeur Hartmann. Paper. Price 52 francs. Pp 323 with 40 illustrations. Paris. Masson & Cie 1936

The author attempts to acquaint surgeons with the knowledge they should have concerning the care of women during pregnancy, labor and the puerperium. Some of the subjects dealt with in the eighteen chapters are the physiology and anatomy of the puerperal state, the diagnosis of pregnancy, extra-uterine gestation, abortion, obstetric injuries, complications during pregnancy, puerperal infections, anesthesia for women in labor, obstetric operations with which surgeons should be familiar, and operations on the new-born. The necessity for such a book is debatable, because all the subjects in it are discussed in detail in all standard textbooks of obstetrics. However, this volume may be of value to general surgeons who have no special interest in obstetric cases but who nevertheless must act as consultants in such cases because of the absence of specialists in obstetrics in their locality. The book is well written and demonstrates that the author, who is an obstetrician, fully understands the attitude of general surgeons regarding puerperal women.

A System of Clinical Medicine Dealing with the Diagnosis Prognosis and Treatment of Disease for Students and Practitioners By Thomas Dixon Savill M.D. Edited by Agnes Savill M.D. and E. C. Warner M.D. F.R.C.P. Tenth edition. Cloth Price \$9 Pp 1114 with 180 illustrations. Baltimore. William Wood & Company 1936

Any book that can go through ten editions must have many things in it which have proved helpful to students and practitioners of medicine. It is interesting to note that in 1912 Miss Savill was able to revise the book with only three collaborators, while in 1936 she had to accept the help of seventeen. All of this goes to show how, with the tremendous advance in knowledge, the day has passed when one man can write well or authoritatively on more than a few phases of medicine. In the plan and arrangement of this book, disease has been approached largely from the standpoint of symptomatology, the idea being to help the student to trace from effect (symptoms) to cause. As a result, the book is in many ways a cross between a treatise on diagnosis and a system of medicine. This, of course, makes it particularly attractive to the intern or practicing physician who finds himself puzzled about a patient who has, let us say, diarrhea. It is helpful then to turn

to one chapter where all the various possibilities are mentioned and discussed. Obviously even in a book of a thousand pages it is impossible to give an adequate description of any one disease and its treatment, and hence it would be easy for any consultant, highly skilled in a particular field, to point to deficiencies and inadequacies in the particular chapter which covers his chosen subject. In the present volume one will rather marvel at the amount of information crammed into the book and offered in a readable form. It probably was a good idea to print in finer type the details about the rarer diseases, the undergraduate student is less likely then to bog down in a morass of detail about diseases like bilharziosis or Oroya fever, which he may not see in a lifetime. Another excellent practice is the printing in boldface of certain words that help the reader to find his way quickly to the essential points for which he is searching. It may not suit an editor who loves artistic printing, but it delights students, and the book was supposedly written for them and not for the Grolier Club. In this volume a remarkable variety of fonts are used to bring out and call attention to the many subdivisions of each subject. The book has a full index, such as is much needed in a reference book of this type.

History of Modern Morals By Max Hodana. Translated by Stella Browne. Cloth Price 12s 6d Pp 338. London. William Heinemann, Ltd 1937

The volume is divided into nine chapters, a preface and an epilogue. The chapter concerning the secret of generation is a brief analysis of our present knowledge of genetics. Unfortunately the author accepts much printed material by Steinach, Voronoff, Benjamin and others which is in no sense of the word established. The second chapter is a history of the general attitude toward homosexuality, based largely on the writings of Hirschfeld. Here again the author reveals inability to distinguish between what is mere medical gossip and what is scientifically established. His next chapter concerns the battle against venereal disease followed by chapters on a sex consultation center, a history of birth control, the fight for recognized abortion, sex education, the analysis of the sex tabu and the patriarchate in dissolution. The book is a strange mixture of narrative writings, essays and a certain amount of dependable factual data. In his final chapter the author tries to relate the attitude of the world to present governmental fascism and communistic policies. He believes that the Russian form of collectivism will lead to the sexual science of the future in which the keynote will be separation of sexual activity from reproduction. In his epilogue the author recognizes that he may have misinterpreted or made errors of fact and he asks that corrections be sent to him care of his publisher.

The Avitaminoses The Chemical Clinical and Pathological Aspects of the Vitamin Deficiency Diseases By Walter H. Eddy Ph.D. Professor of Physiological Chemistry Teachers College Columbia University and Gilbert Daildorf M.D. Pathologist to the Grasslands and Northern Westchester Hospitals Westchester County New York. Cloth Price \$4.50 Pp 338 with 32 illustrations. Baltimore. Williams & Williams Company 1937

This book affords up to the minute information about the chemical nature of the vitamins and the pathologic aspects of the vitamin deficiency diseases. The authors are described on the title page as a physiologic chemist who is director of the Bureau of Foods and Sanitation of *Good Housekeeping Magazine* and a physician who is also a pathologist.

The chapters on vitamin C are particularly well done, especially the section on subclinical scurvy. The chapters on pellagra, however, appear to be somewhat biased and incomplete. The authors emphasize reports on the histologic similarity in the skin lesions of pellagrins and of animals on experimental diets and apparently minimize references to dietary factors other than the vitamin G complex or recent non nutritional concepts of the etiology of pellagra. The chapters on the morbid effects of certain complicated dietary experiments and on vitamins in relation to blood regeneration are so sketchy that they might well have been omitted. The three chapters at the end of the volume describe briefly the methods used in the assay of food products for vitamins, and various clinical tests that have been introduced within recent years. It is interesting to note that the vitamin E unit of Pacini and Lind is described, although it is well known that this unit has no

generally established recognition in scientific circles. The descriptions of the pathologic changes occurring in tissues in vitamin deficiency diseases are at times uncritical, some of the descriptions of the pathologic changes sound like a catalogue of reported observations rather than a critical presentation of the progressive changes in the tissues in vitamin deficiencies.

Each chapter contains a brief bibliography, useful but incomplete and in some places with minor typographic errors. For example, H J Gerstenberger is listed on page 120 as H J Gerstenberg, and A J Carlson is listed on page 84 as A J Carlsson.

Quelques vérités premières (ou soi disant telles) sur les maladies du foie. Par Noel Fliessinger, professeur à la Faculté de médecine de Paris. Collection publiée sous la direction de MM L Ombredanne et N Fliessinger. Paper. Price 24 francs. Pp 81. Paris: Masson & Co. 1936.

This is an interesting and unusual book in that it consists entirely of aphorisms with regard to the diagnosis and treatment of diseases of the liver. In many ways the idea looks good, the statements are short and pithy, and students and busy practitioners can absorb information quickly. The maker of aphorisms delights, of course, in such statements as "a cirrhotic does better when his arms and face get fat, or a reddened state of the buccal mucosa at the beginning is a bad sign indicating the coming of hepatic insufficiency." There is always the danger, of course, that such a statement is more striking than true. Under treatment, Fliessinger makes such useful and true statements as "a milk diet is a bad one because it constipates, it should be used only as a last resort. Sugar is the best food for the liver. One must not operate on patients with signs of severe hepatic insufficiency and marked tendency to bleeding. Anesthesia with chloroform or ether is particularly undesirable. The hepatic patient is never entirely cured by any operation." Unfortunately, the author does not seem ever to have heard of liver function tests. He takes no delight in duodenal intubation and the study of A and B biles. He advocates a rather odd way of giving the dye for cholecystography—in small doses over several days. Perhaps the best aphorism in the book is from Chauffard, who says that "a physician may sin through ignorance but he should never sin through negligence."

The Chemistry of Natural Products Related to Phenanthrene. By L F Fieser. Associate Professor of Chemistry, Harvard University. With appendix. Second edition. Cloth. Price \$7. Pp 456. New York: Reinhold Publishing Corporation. 1937.

This excellent treatise, the first edition of which appeared only a year ago, has been revised with the addition of a ninety page appendix to include the new literature up to Jan 1, 1937. Minor changes have also been made in the original text. As pointed out in the review of the first edition (*THE JOURNAL*, Aug 26 1936) the author has handled a difficult subject with remarkable facility, the result is a concise and lucid dissertation on the naturally occurring sterols and related substances. Those who desire to keep abreast of the rapid and extremely important developments in the chemistry of the estrogens, androgens, cardiac glucosides, bile acids, carcinogenic substances and the like will find this book indispensable. It contains in readily available form material not elsewhere accessible in one volume.

Inhalation Anesthesia. A Fundamental Guide. By Arthur E Guedel. MD. Associate Clinical Professor of Surgery (Anesthesia), University of Southern California School of Medicine. Cloth. Price \$2.50. Pp 172. New York: Macmillan Company. 1937.

This valuable book, which deals specifically with inhalation anesthesia, informs one of the mechanism of this method of anesthesia, the stages of anesthesia, signs of anesthesia, depth of anesthesia required for control of surgical reflexes, depth of anesthesia necessary for various surgical procedures, potency of the various anesthetic agents, the mechanism of various anesthetic requirements, the preparation of the patient and the selection of the anesthetic agent, and of the accidents due to changes in blood pressure during anesthesia, ventricular fibrillation, central respiratory failure, accidents due to peripheral respiratory interference, nitrous oxide in obstetrics, breath holding, pharyngeal spasm, laryngeal spasm, tongue swallowing, aspiration of debris, respiratory interference by mucus, aspiration of

pus from the pharynx, aspiration in lung surgery, aspiration of blood, aspiration of sponges, packs, teeth and suction tips, miscellaneous accidents, massive atelectasis, tracheal collapse, convulsions under anesthesia, status lymphaticus, embolism, idiopathic paroxysmal tachycardia, liquid ether into the lungs, the vapor of heated ether, injuries to the eyes, postoperative hyperthermia, cerebral asphyxia, cyanosis, anesthetic explosions, the explosibility of various anesthetic agents, and the sources and prevention of ignition of anesthetic gases and vapors, with illustrative cases. In the back of the book there is a list of selected references, followed by an index. The book should be owned by every person administering general anesthetics and should be read and reread. It will serve better than any other available publication as a textbook for students and as a reference book for anesthetists specializing in anesthesia.

Medical Greek and Latin at a Glance. By Walter R Agard. B Litt. Professor of Greek, University of Wisconsin. With an introduction by C H Bufling. MD. Professor of Pathology, University of Wisconsin. Second edition. Cloth. Price \$1.50. Pp 87. New York: Paul B Hoeber Inc. 1937.

A familiarity with this little work will fortify a reader against any surprises as medical terminology expands with the development of medicine. The method of putting the elements of words together is presented. Prefixes, suffixes and the combining forms of medical terms are introduced and translated. A first reading will tempt one to regard the word lists with closer attention and to undertake the bits of memorizing essential to the acquirement of a vocabulary. It is a fascinating process that can be a matter of improving odd moments and is aided by the form of the book, the reading matter of which is in typewriter type on the right hand pages, with space for notes on the left. The Greek letters are especially easy to recognize. A list of books is suggested for the light they throw on the influence of the Greeks and the Romans on the development of medicine.

Die Veranlagung zu Krampfanfällen. Von Dr Friedrich Mauz. a o. Professor für Psychiatrie und Neurologie in Marburg. Boards. Price 2.80 marks. Pp 68. Leipzig: Georg Thieme. 1937.

This little book attempts to examine the relative roles of heredity and external environment on the production of convulsions especially epilepsy. The first portion is devoted to examination of the bodily constitution of patients and their relatives. The second portion is clinical and examines the different forms of the disease and the external factors that influence the constitutional structure. Final conclusions are not provided. The factual data included in this monograph are not convincing, but those who are especially interested in this subject may wish to consult it.

Life and Death. The Autobiography of a Surgeon. By Andrea Majocchi. Translated by Wallace Brockway. Cloth. Price \$2.75. Pp 300. With one illustration. New York: Knight Publications. 1937.

The surgeon who contributes here his reminiscences is a friend of D Annunzio and of Mussolini. He is a leader among the surgeons of Italy and quite obviously possessed of the poetry and romance usually associated with the Latin temperament. His father was a country practitioner who died of an infection sustained during his surgical work. On his death bed his father said he would rather have his children be peasants than doctors. Nevertheless when the boy after being reared came to choose a vocation he gravitated naturally into medicine. He describes brilliantly his service as assistant in the maternity center in Milan and then the course by which he became a general surgeon. In 1909 early in his career, he made a brief visit to the United States and was immensely pleased by the work he saw at the Mount Sinai Hospital in New York. He deprecates the routine of the Mayo Clinic and of all systematic medicine. Indeed, his book is a constant plea for individualism and for the physician as an artist rather than as a technician. No doubt many of the public will be impressed by the chapter devoted to incidents in surgical practice because the author has an unusual ability to dramatize the most commonplace medical affairs. His book is vital and moving, the section devoted to descriptions of medical assemblages and congresses are satirical and humorous. For the casual medical reader the book may be especially recommended as one that will hold his interest to the end.

Marriage and Periodic Abstinence The Natural Method of Scientific Family Regulation By J G H Holt MD Gynaecologist and Sexologist at Bilthoven The Hague and Haarlem (Holland) Cloth Price \$3 8s 6d 1p 174 New York Toronto & London Longmans Green & Co 1937

Here is another book dealing with the safe period as a system of birth control. It emanates from Holland. The author has collected the available periodical literature and other observations made throughout the world on this subject. He discusses the various methods of calculating the safe period, recognizing the danger of the influence of suggestion on the average layman. He feels that the method can be practiced safely only when the system is controlled by an expert for from six to twelve months before undertaking the practice regularly. While his book will be of interest to the physician, the average lay reader will find it more confusing than any other of the volumes thus far available on this subject.

A Manual of Radiological Diagnosis for Students and General Practitioners By Ivan C C Tchaperoff MA MD DMRE Assistant Radiologist and Radium Registrar St Thomas's Hospital London. With a foreword by Philip H Mitchner MD MS FRCS Surgeon to St Thomas's Hospital. Cloth Price \$6 Pp 256 with 286 illustrations Baltimore William Wood & Company 1937

This is a valuable little manual with discussion of clinical material arranged on an anatomic basis. There is a brief chapter devoted to a summary of x-ray physics, technique and radiographic difficulties. The amount and wealth of clinical material presented is surprising for such a small volume and speaks for the careful organization and singular clarity of the book. The reproductions of the roentgenograms are excellent and the normal and pathologic details are carefully pointed out. Occasionally a small line drawing appears further to illustrate a point. The subject matter is almost wholly in outline form, permitting rapid gleaning of the essential diagnostic and significant features without a host of technicalities. Although more than half the book is devoted to bones and joints, other systems are not neglected and differential diagnosis is emphasized.

Your Everyday Speech By William Norwood Briggance Ph D Cloth Price \$2 50 Pp 230 with 15 illustrations New York & London Whittlesey House McGraw Hill Book Company Inc 1937

Much of the material in this book has appeared previously in the *Woman's Home Companion*, the *Ladies Home Journal* and the *Southern Speech Bulletin*. The author has been a leader in his field for many years. He discusses a number of forms of American speech and the various dialects that exist in different parts of the country and speech standards. He analyzes the reasons why many people mispronounce and make certain sounds off key. One section of the book is devoted to speech defects. Especially useful are the chapters on pronunciation. The book will certainly be found helpful by all interested in this subject.

Atlas der Augenkrankheiten Sammlung typischer Krankheitsbilder mit kurzen diagnostischen und therapeutischen Hinweisen Von Dr Rudolf Thiel ord Professor an der Universität Frankfurt a M Cloth Price 24 marks Pp 197 with 420 illustrations Leipzig Georg Thieme 1937

In the preface to this excellent volume the author states that the work is designed to enable students and practitioners to have available at all times in a handy form lifelike pictures of the most frequent lesions of the eye, drawings or the most common operative procedures, short notes on differential diagnosis, and a statement as to the treatment of the condition. It strives in no way to replace the standard textbooks. The author has increased the value of the work by its unique arrangement. On the page opposite each illustration is a short remark as to treatment and the like, with space allowed so that the reader may make additions for future reference. In this way the text may be kept up to date. The volume is divided into eleven chapters, on diseases of the lid, the lacrimal apparatus, the orbit, the conjunctiva, the cornea, the sclera, the iris, the lens, the vitreous, the optic nerve and retina and the choroid. The drawings of the various operative procedures on the lid are simple but clear, and the originator of each operative procedure is named. Excellent black and white and also colored photographs illustrate the conditions of the lid. The anatomy of the lacrimal apparatus is well depicted, drawings of manipulative

and operative techniques are shown, together with photographs both in black and white and in color of the various disease pictures. To illustrate conjunctival infections there are colored photographs of the etiologic organism and of pathologic specimens. The various types of cataract are well illustrated in the chapter on the lens. The colored plates of conditions of the fundus are the best found in any textbook. Choroidal disease is depicted in an admirable manner. The text is brief and to the point, without involved descriptive sentences. An adequate index is appended. The book is a worthy and useful atlas of the eye.

Feeding Diet and the General Care of Children A Book for Mothers and Trained Nurses By Albert J Bell A B MD Associate Professor of Pediatrics in the Medical College of the University of Cincinnati Third edition Cloth Price \$2 Pp 316 with 7 illustrations New York G P Putnam's Sons 1936

Books on the feeding and care of children are myriad, and the mother is confronted with the problem of which of the numerous texts to follow. This one, written to meet the needs of mothers as well as of trained nurses for maternal or infant care, will probably fulfil this function as well as any other. The material has been revised, and additional chapters on behavior in early childhood and on dentistry have been added. The information is conveniently arranged and is easily followed. Occasional errors have crept into the text, such as the statement that "an umbilical hernia is, in most cases, outgrown" or that "an inguinal hernia may be relieved by hot applications over the affected part."

Scalpel and Sword By Sir James Elliott Cloth Price \$2 50 Pp 215 Sydney Australia Angus & Robertson Limited 1936

This autobiographic sketch tells the story of a New Zealand surgeon who was trained in Edinburgh University and later served on the staff of a field hospital during the war in South Africa. In the Great War he was senior medical officer of a hospital ship. His story includes a beautiful description of the scenery of New Zealand, which is his home, and some fine discussion of the folklore and religious beliefs of the Maoris. The style is attractive and the descriptive accounts are enlivened with numerous excellent anecdotes. The sixteenth chapter is entitled "Among the Americans." The author came to this country in the group with Hunter and Royle. In his description of his American tour he amuses himself with the American dialect and American customs but no more than we amuse ourselves with those of New Zealand and England.

The Fundamentals of Personal Hygiene including Their Practical Application to Healthful Living By Walter W Krueger Ph B Instructor in the Grand Rapids Junior College Second edition Cloth Price \$1 75 Pp 204 with 60 illustrations Philadelphia & London W B Saunders Company 1936

This book was primarily prepared for elementary students, to present to them the principles of personal hygiene and to serve as a guide to healthful living. Originally the book was prepared so that it would be especially suited to the needs of girls, in the second edition the necessary changes have been made to meet the needs of boys as well. Other alterations have been made to keep the subject matter abreast of the field of hygiene. In the book are discussed, in a clear, authoritative fashion, matters relating to personal hygiene, such as posture, exercises, clothing, care of the skin, nutrition, sunlight, mental health, recreation and sex hygiene with a short chapter on health fads, fancies and follies. The bibliography and questions for class discussion add to the usefulness of the work as a textbook.

Physical Therapeutic Methods in Otolaryngology By Abraham R Hollender MD FACS Associate in Laryngology Rhinology and Otolaryngology University of Illinois College of Medicine Cloth Price \$3 Pp 442 with 189 illustrations St Louis C V Mosby Company 1937

In the first part of this book the principles underlying the use of physical agents and their effects are discussed and much valuable information of a theoretical and practical character is given. The second part relates to the special use of physical agents in the field of otolaryngology. Some of the material is not relevant to the subject. Some of the claims made for the methods employed are open to question. Almost any accepted treatment for acute rhinitis, for instance, is likely to give good results, because the course of this illness is usually

short and self limited. There are some statements to which exception may be taken. For example, not every one will agree, as stated on page 271, that "boils in the external auditory canal are usually associated with some metabolic disease, especially diabetes." Apart from these minor exceptions there is much that is valuable and applicable. Physical therapeutic methods are being properly assessed and are of increasing aid to the practitioner. The interested specialist may read this work with much profit.

Original Papers of Richard Bright on Renal Disease. Edited by A. Arnold Osman D.S.C. F.R.C.P. Cloth. Price \$7.25. Pp. 172, with illustrations. New York & London: Oxford University Press, 1937.

In this volume are reprinted four articles by Richard Bright, printed in 1827, 1833 and 1836. In the appendix there are reproductions of histologic sections of three cases of Bright's disease originally described by Dr. Bright. The book is beautifully printed in the best tradition of the Oxford Press, handsomely illustrated with colored plates and halftones. It should be of interest to every one interested in the history of internal medicine or in its practice.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Workmen's Compensation Acts. Rupture of Duodenal Ulcer Attributed to Strain.—The claimant attempted to lift a pump to place it on some planks so that he could better clean it. Both his hands and the pump were greasy, and it started to slip. In order to prevent its falling, he twisted himself in an abnormal position and felt something "give away" inside him. He became nauseated and was unable to walk for a few minutes. Finally he told a fellow workman that he was ill and would have to go home. Before he could reach his home, however, he felt so much worse that he asked to be taken to a hospital. Shortly thereafter an operation was performed on him which disclosed a rupture of a duodenal ulcer. Thereafter he filed a claim with the industrial commission and the matter was referred to the medical advisory board. One member of the board gave the claimant an external physical examination and examined the several roentgenograms which had been taken of him, studied the hospital records of the case and consulted with the physician who had operated. The member of the board who made this examination reported that the claimant had a "pathological process" before the accident and that the condition which developed would have developed whether the claimant had been at rest or was lifting. The medical advisory board on the basis of this report concluded that the condition suffered by the claimant was not due or influenced by any accidental injury. Whereupon the commission denied compensation and the claimant appealed to the Supreme Court of Arizona.

There is no question, said the court, that shortly or immediately after the claimant suffered strain in lifting the pump he became nauseated and vomited blood that he was immediately taken to the hospital and given an exploratory abdominal operation, and that the physician who operated reported that there had been some kind of extravasation of blood into the tissues "between the duodenum and the perineum." To the ordinary layman, observed the court, this would certainly indicate that there was some causal connection between the strain and the abdominal condition. But, the court said, the cause of the physical condition of the claimant was, to a great extent at least, a matter of opinion and not positive knowledge, and expert medical opinion on the subject was certainly competent evidence that the commission had the right to consider. The only medical testimony offered was that of one member of the medical advisory board who had examined the claimant and the medical records of the case and had discussed them with the operating surgeon. The conclusion of the medical advisory board was unanimous that the condition disclosed as the result of the operation was not produced by the strain which preceded

it. The industrial commission had the right to accept the opinion of the board and the court felt disinclined to reverse the finding of the commission.—*Wiggins v. Pratt-Gilbert Hard ware Co.* (412), 62 P. (2d) 124.

Roentgenograms Admissibility in Evidence.—Before a roentgenogram may be admitted in evidence, said the Supreme Court of Idaho, it must be shown by competent evidence that the roentgenogram was taken by the method and in the manner generally recognized in roentgenography. It is a mere use of idle and meaningless language to say that a witness who identifies a roentgenogram must be able to state that it is a correct representation of the object it purports to picture, for obviously it purports only to show shadows of objects not otherwise visible to the eye. A witness cannot truthfully say that a roentgenogram is "a true and correct representation of the object it purports to show" unless it is conceded that he bases his statement on the scientific fact that the roentgenogram does as accurately picture the object's shadow as does the photograph picture an object's external surface. Roentgenograms properly interpreted to the jury are very valuable evidence in a case, because of the manner in which they enable the jury to visualize an injury or condition under investigation.

The science of roentgenography is too well founded and generally recognized, continued the court, to render it any longer necessary for a witness to testify to the reliability and trustworthiness of roentgenograms as such before admitting them in evidence. It must first appear that the roentgenogram was taken of the thing or object under consideration, and that it was made by the usual method or process. The position of the body at the time roentgenographed should be shown. Ordinarily, roentgenograms are of no use and should not be presented to the jury unless they are interpreted and explained to the jury by a competent witness. Persons who follow the profession of making roentgenograms are usually qualified to interpret them, in the opinion of the court. So also are the average physicians, although being a physician does not in itself qualify a witness as a competent interpreter of a roentgenogram.—*Call v. City of Burley (Idaho)* 62 P. (2d) 101.

Assault and Battery. Physician's Liability for Operating on Minor Without Consent of Parent.—The appellee, a boy, aged 14 years, sustained a fracture of his leg a few inches above the ankle, in an automobile accident. He was taken to the appellant's hospital about 15 miles from the scene of the accident. The appellant was called to the hospital and amputated the "foot." Thereafter, the appellee, by his father and guardian, instituted this action against the appellant to recover damages. The petition set out two causes of action, one for assault and battery, alleging that the operation was performed without the consent of the boy's parents, and the other for malpractice. The jury found for the boy on the first cause of action and the physician appealed to the Supreme Court of Oklahoma.

The physician testified that he was called to the hospital about midnight and found that the boy's right leg was crushed and mangled that the muscles, blood vessels and nerves were torn and some of the nerves severed, and that the foot had no circulation. He considered an immediate amputation necessary, he testified, to preserve the life and health of the boy. In this testimony he was corroborated by the testimony of two nurses and an assistant who was not a physician. No roentgenograms were made. Three reputable surgeons approved, by way of expert testimony, the procedure adopted by the appellant physician. The operation was admittedly performed without obtaining the consent of the parents of the boy, but the physician testified that he told the boy that an amputation was necessary and that the boy said to go ahead and do whatever was right. The boy denied even discussing an amputation. He testified that an assistant at the hospital, a physician, told him that he would have to put him to sleep to set the leg and that the next thing he knew was about 9 o'clock the next morning when he awoke and discovered for the first time that his foot had been amputated. He did not see the appellant, he testified the night of the accident and did not see him until the second day after he was taken to the hospital. After the accident he said his leg was not swollen but gave him considerable pain. Very little bleeding occurred and the boy testified that, on the way

to the hospital, he was able to "wiggle his toes" Other lay witnesses testified to the fact that the fractured bone was sticking out of the boy's leg about an inch, that the wound bled only a few drops, and that the leg was not swollen and was not turning black A reputable surgeon, testifying in answer to a hypothetical question embodying the facts disclosed by the lay witnesses, stated that he would not have amputated the foot

The appellant physician contended that the trial court erred in instructing the jury that as the amputation was immediately done without express consent and that, since the appellant sought to justify the amputation on the ground of an emergency or implied consent, the burden was on him to prove the existence of an emergency by a preponderance of the evidence The appellant admitted, the court said, that he performed the operation, or committed the assault, but sought to excuse himself or justify the procedure on the ground that there was an emergency This being the case, the burden was on him to prove by a preponderance of evidence that an emergency existed The instructions given by the trial court were therefore correct The appellant further contended that the evidence of the lay witnesses was incompetent and that the testimony of the expert witness for the boy, based on the lay testimony, was likewise inadmissible But, said the court, a lay witness may testify to an objective fact, he certainly has a right to use his senses the same as an expert witness He can see a broken bone, he can tell whether it sticks through the skin or whether it doesn't, he can see whether there is any discoloration or whether there is any bleeding Most certainly, the boy was competent to testify that he could wiggle his toes There was no error in admitting this testimony Furthermore, the court said, it was proper for the expert witness to base his testimony on the testimony of the lay witnesses The conflicting testimony presented a question of fact for the jury and, the jury having decided the issues for the boy, the Supreme Court felt disinclined to interfere with the verdict The judgment of the trial court was therefore affirmed—*Rogers v Sells (Ola)*, 61 P (2d) 1018

Workmen's Compensation Acts Pulmonary Abscess in Relation to Trauma, Credibility of Expert Testimony—The claimant was struck on the chest by a crate of lettuce in the course of his employment with the Western Vegetable Distributors Shortly thereafter he complained of pain in his side He did not consult a physician until nineteen days later Dr Hughes, the physician consulted, sent him to a hospital and diagnosed his condition as a ruptured blood vessel in the lung with blocking of a bronchial tube by a clot of blood, resulting in a pulmonary abscess Some time later, he was examined by another physician, Dr Holmes On the basis of this examination, the history of the case, and roentgenograms, Dr Holmes believed that the claimant's condition was due to a pneumonia with possible small abscess formation Eventually the claimant instituted proceedings under the workmen's compensation act of Arizona From an order of the industrial commission denying compensation, the claimant appealed to the Supreme Court of Arizona

Dr Hughes testified that, based on the history of the case, the blow on the chest was the original cause of the claimant's pulmonary condition Dr Holmes, however, testified that it was improbable that the claimant's pulmonary condition was due to the blow He pointed out that a pneumonia following a severe contusion to the chest is possible but quite rare, that a pneumonia due to trauma would be expected to supervene within three or four days or at most a week from the time of the accident, that any injury to the chest not sufficient to cause the workman to stop working would be most improbable as a cause of pneumonia two weeks later, and that abscess formation following an injury to the chest is rare The claimant contended that the commission should have accepted the positive testimony of the one physician that the injury caused the pulmonary abscess, rather than the testimony of the other physician that it was extremely probable that the injury did not cause the abscess There might be some merit to this contention, said the Supreme Court, if the point at issue was one which was subject to positive knowledge But where the question is necessarily one of opinion, a trier of fact is not required

to give more weight to an opinion that is expressed more positively than another When two expert witnesses reach opposite conclusions, a trier of fact, in deciding which witness is more probably correct in his conclusion, may consider the experience of each witness and their interest or bias, conscious or unconscious, in the result to be reached

The court could not agree with the claimant's further contention that the industrial commission was not a fair and impartial tribunal because, on its past record, it had invariably accepted the testimony of its own medical adviser and its medical rating board as against that of medical witnesses appearing for claimants The commission, said the court, presumably chooses its medical adviser because it has confidence in his integrity and ability His salary is fixed and he has no pecuniary interest in the outcome of the case The members of the commission's medical rating board, the final medical authority whose opinion in doubtful cases the commission is apt to accept even in preference to that of its own chosen adviser, are selected by the president of the state medical association and their compensation is fixed and paid by the commission regardless of the nature of their recommendations Any tendency of the commission to accept the opinions of its own experts rather than those of a claimant's experts, though the witnesses be of equal standing in their profession, may be explained on the theory that the commission believes that a claimant's witness is more apt to be mistaken in his judgment than a witness who has no financial interest in the nature of the award, has not been chosen because of a previously expressed opinion in the case and whose testimony will be used in all cases which he examines, regardless of whether it favors a claimant or not

Accordingly, the Supreme Court affirmed the award of the commission denying compensation—*Ison v Western Vegetable Distributors (Ariz)*, 59 P (2d) 649

Workmen's Compensation Acts Compensability of Loss of Vision in Previously Injured Eye—While he was working as a pressman for the defendant company, a piece of steel entered the claimant's right eye The state industrial board awarded him compensation for 100 per cent permanent loss of use of that eye On appeal, the Court of Appeals of New York, in affirming the award, held that the complete loss of use of the claimant's eye was the natural and unavoidable result of the injury and that he was entitled to compensation for 100 per cent permanent loss of use of that eye even though there was evidence that he was industrially blind in that eye prior to the accident as the result of a previous injury—*Pyshtack v Henry Forge & Tool, Inc (N Y)*, 4 N E (2d) 729

Compensation of Physicians Liability of Client for Fees of Medical Expert Employed by Attorney—A physician employed by an attorney to act as a medical expert to assist him in contesting a will on the alleged ground of mental incapacity on the part of the testator may hold the attorney's client for the reasonable value of his services, in the absence of a showing that the physician had notice of an agreement between the attorney and his client limiting the attorney's authority or that the physician agreed to look solely to the attorney for his compensation—*Herfurth v Horne (Ky)*, 98 S W (2d) 21

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers in continental United States and Canada for a period of three days. Periodicals are available from 1926 to date. Requests for issue of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them. Titles marked with an asterisk (*) are abstracted below.

Variability of Vital Capacity of Lungs—Arnett and De Orsay base their study on yearly vital capacity readings in 100 men and 100 women of college age. At least three, and frequently more, readings were made in each case. Students in whom there existed any suspicion of disease which might affect the vital capacity were omitted from consideration. Nineteen of the men and thirty-two of the women exhibited standard deviations of less than 20 cc from the best straight line. This group could be further subdivided into ten men and fourteen women who exhibited no vital capacity change whatever, four men and four women who exhibited a uniform gain, and five men and fourteen women with small irregular variations. Apparently the cases tend to follow a normal distribution. In pneumonia the fall in vital capacity usually amounts to from 1,000 to 3,000 cc. The greatest standard deviation exhibited by any student in the present study was 235 cc. The vital capacity might therefore be used with propriety in any of these 200 students as an aid in the diagnosis of pneumonia. On the other hand, in the early stages of pulmonary tuberculosis, in which physical signs may still be indefinite and the vital capacity loss as low as 250 cc, the test would be helpful only in those students whose vital capacities were known to vary but little, here it would be proper to exclude from consideration any whose standard deviation

from the best straight line exceeded 83 cc. This would mean the exclusion of thirty-two of the men and twelve of the women of the present study. When disease is suspected and the vital capacity is found to be lower than on previous occasions, the authors have learned to scan the previous vital capacity determinations in the patient's record to see whether variations comparable in magnitude have occurred in the past. If so, little or no weight is attached to the finding, even though the figure may be well below the individual's average. If, on the other hand, a similar vital capacity fall is observed in an individual whose determinations have remained comparatively constant, it is taken seriously. Used in this way, it is believed that in university health services and in offices of physicians who have an opportunity to examine their patients at intervals, particularly if their patients come to them for an annual health examination, the test will be found of value.

Primary Tuberculous Appendicitis—Thieme has encountered seven cases of so called primary tuberculous appendicitis, in two of which tuberculosis elsewhere was found later. The history and physical observations in these seven cases were essentially the same as in pyogenic appendicitis and the diagnosis was not made preoperatively. The prognosis was uniformly good. Twenty cases of pulmonary tuberculosis in which operations for appendicitis has been performed were reviewed. The lesion was acute in thirteen and recurrent in seven. Of the twenty patients, six had tuberculous appendicitis, five of them were doing poorly preoperatively from their pulmonary standpoint. Of the six, five are dead and the sixth is critically ill. The extremely poor prognosis of tuberculous appendicitis in advanced, uncontrolled pulmonary disease is evident. The fourteen cases of pyogenic appendicitis occurred in patients who were doing well from the standpoint of their pulmonary tuberculosis. Their subsequent course has been such as to lead the author to believe that their appendicitis was unrelated to their tuberculosis and did not affect the course of that disease.

Analgesia with Barbituric Acid Derivatives in Labor—Montgomery asserts that doubt has arisen from various sources as to the effect which deep analgesia and anesthesia have on the intelligent and safe conduct of labor. The Committee on Public Health Relations of the New York Academy of Medicine state that the use of anesthesia during labor and delivery has grown steadily in extent since its introduction in the last century and is a problem of the most pressing importance. This has come about to a large extent through pressure from the lay public. The women of large urban centers have become steadily more insistent in their demands for shorter and less painful parturition, and the obstetrician may disregard these demands only at great risk to his own practice.

The committee is of the opinion that "frequent and injudicious employment of deep analgesia and anesthesia has increased very materially the rate of operative intervention and has on this account been a major factor in preventing a reduction in the high maternal mortality rate in this country." In the light of relentless scrutiny, it appears uncertain that deep analgesia with the barbiturates is completely safe or fully reliable. It is questionable whether the widespread acceptance of this method is a step forward in obstetric practice.

Contraction Ring Dystocia—McKenzie states that in 14,080 deliveries on the obstetric service of the Louisville City Hospital between Jan 1, 1926, and Sept 30, 1935, there were thirty-six cases in which the contraction ring was palpated. Since Jan 1, 1931, twenty cases have been treated by hypodermic injection of epinephrine, sixteen cases prior to that time were treated by other methods. The use of epinephrine to relax a contraction ring has led to a decrease in the maternal mortality rate. Although the fetal mortality is still high, fewer craniotomies were necessary on living babies and more babies were discharged alive and well. Although epinephrine may relax the muscles in a retraction ring, the cause of dystocia is not removed and the case is still formidable. In dystocia due to contraction ring, epinephrine relaxes the ring and thus removes the cause. The case may terminate by spontaneous or operative delivery, depending on the condition of the patient and the judgment and skill of the obstetrician.

Establishment of Diurnal Temperature Cycle—In attempting to elucidate the mechanism responsible for the development and persistence of the diurnal cycle Kleitman and his associates found that it runs parallel with the diurnal body temperature curve and diurnal variations in steadiness and performance of muscular and mental tasks. The present report deals with the time of establishment of the diurnal cycle, as

judged by the appearance of a definite diurnal body temperature curve, in the human subject. In a general way the group average of the diurnal temperature range increases with age but during the second year of life there appears rather abruptly a marked increase in the magnitude of that temperature range, which is now almost doubled in value and definitely exceeds that of older children and adults.

Antigonococcus Serum, Gonococcus Vaccine and Filtrate in Gonococcal Infections—Keefer and Spink found that the addition of antigenococcus serum to blood in vitro will increase the bacteriolytic titer of the blood serum. When antigenococcus serum is injected intravenously the titer can be increased, and this is true of individuals with and without bacteremia. In this way it is possible to sterilize the blood of some patients provided they do not have endocarditis. An increase in the bacteriolytic titer of the blood was observed in one patient following the intravenous injection of vaccine, but it was not possible to demonstrate a similar response in another when the vaccine was given intradermally or subcutaneously. The authors were unable to demonstrate an increase in antibodies following the injection of Corbus-Ferry filtrate. In two patients with local gonococcal infections they were unable to sterilize the lesions with antigenococcus serum. This may have been due in part to the presence of large amounts of mucus and fibrin which protect the organism from the antibodies. Antigonococcus serum should be used in cases of gonococcal bacteremia, especially when there is no evidence of endocarditis. When vaccines are used, it would appear that intravenous injection would be better than intradermal or subcutaneous inoculation. They were unable to show that serum was capable of sterilizing the synovial fluid when it was injected directly into the knee joint, and they had a similar experience in a case of gonococcal ophthalmia. An increase in the antibodies of the blood by injecting gonococcus filtrate intradermally could not be demonstrated.

Incidence of Syphilis in the Negro—From September 1926 to August 1933, blood from 13,728 patients from the hospital wards and the outpatient clinics was tested in the laboratory of Holloway and his colleagues. They found that of this number 3,534, or 27.4 per cent, gave a positive reaction to one or more of the tests (Wassermann, Eagle and Hinton) used. If the one plus cases are considered doubtful, the total percentage of positive cases would be 22.1, 70 per cent of this positive group stated that they were without knowledge of the fact that they were syphilitic. Likewise only 13 per cent of those with positive reactions had received antisyphilitic treatment before their blood was submitted to the laboratory. The patients were divided into two groups: the patients from the clinics and hospital wards and the healthy, more intelligent student group (836) from several Negro colleges. The incidence of syphilis in the select student group was 5.9 per cent. The incidence was less than 2 per cent among the women of one college.

Postarsphenamine Jaundice—According to Soffer, of a total of 18,250 patients who received antisyphilitic treatment in the Johns Hopkins Hospital from 1919 to 1934, 158 developed jaundice, an incidence of 0.87 per cent. Arsphenamine causes jaundice one and one-half times as frequently as neoarsphenamine, while tryparsamide shows the lowest incidence of treatment icterus. The percentage incidence of postarsphenamine jaundice is almost three times as great among the white

as among the Negro patients. There is considerable evidence in the literature to indicate that arsenical therapy or accidental chronic arsenical poisoning may produce a progressive disease of the liver even in the absence of a preceding acute icteric episode. Long continued use of arsenical compounds may produce progressive damage to the liver. This hazard is further increased if, during the course of treatment with arsenicals enough liver damage is incurred to produce icterus. Patients who have had an attack of catarrhal jaundice may demonstrate evidence of impaired hepatic function for many years after the jaundice has subsided. The same may be true of patients who at some time or other developed postarsenical icterus.

Surgical Treatment of Facial Spasm—Coleman has had under observation recently five patients with facial spasm. There were three patients with clonic unilateral spasm and two in whom the spasm was bilateral and predominantly of the tonic type. The patients with unilateral spasm sought relief chiefly because of the embarrassment resulting from contraction of the facial muscles, particularly those about the eye. Reading was difficult and the patients were continuously disturbed by the facial grimaces. Many kinds of therapy had been tried without relief. The contractions persisted with variations but with increasing intensity and annoyance. Two of the patients had severe disabling bilateral tonic contractions of the entire facial musculature. Medical treatment and psychotherapy are of no benefit to facial spasm. The condition can be relieved only by paralysis of the nerve by section, or by injection of the nerve with alcohol. With recovery from the paralysis the spasm usually returns, but the patient is

grateful for a period of relief which may last from six to twelve months. The paralysis necessary to the permanent cure of facial spasm should be relieved by anastomosing the facial with the hypoglossal or spinal accessory nerve.

Surgical Treatment of Chronic Biliary Typhoid Carriers—Coller and Forsbeck performed cholecystectomy on eighteen chronic biliary typhoid carriers with cure in 88.9 per cent. No deaths occurred. Eligibility for cholecystectomy was based on the carrier being a gallbladder carrier and a good surgical risk. Cure was considered effected when twelve consecutive specimens of negative feces and at least one (usually two) negative bile specimen were obtained. Most cases become feces negative in from a few days to two or three weeks after operation. Hope for eventual cure may be maintained for many months, however. Mortality and cure percentages are comparable only if (1) typhoid and paratyphoid carriers are considered separately, (2) carriers operated on primarily for cure of the carrier state and primarily for clinical symptoms are considered separately, (3) the time elapsed since typhoid is taken into consideration and (4) the criteria for release are identical or at least similar. Cholecystectomy may logically be recommended as a matter of personal precaution to a chronic carrier without clinical symptoms who is a good risk. Each cure removes one more of a limited number of infection foci and thus contributes to the ultimate eradication of typhoid.

Influence of Gastric Acidity on Iron Retention—In their experiments, Barer and Fowler observed that patients with achlorhydria retain less iron from a normal dietary intake of iron than do patients with free hydrochloric acid in the gastric contents. This diminished retention of iron may play a part in the etiology in certain cases of idiopathic hypochromic anemia, although it is not believed to be the only etiologic factor. With a large intake of iron (500 mg daily) the retention of iron is not influenced by the gastric acidity, and the administration of hydrochloric acid, even in large amounts, does not increase the retention of iron. The latter was true both with normal and with large amounts of iron and indicates that the administration of hydrochloric acid is not necessary for an adequate retention of iron. Nonanemic subjects retained as much iron as did patients with anemia from a normal intake of iron as well as when large amounts of iron were administered. Of five patients on a low intake of iron, from 381 to 667 mg daily, in negative balance, the four who were placed on a diet with a normal content of iron subsequently showed a positive balance. This indicates that an intake of 67 mg a day is not sufficient for the needs of these patients.

Absorption of Fat from Ileum—Doubilet and Reiner encountered a patient who had accidentally acquired a temporary Thury fistula of the middle portion of the ileum during treatment for strangulated femoral hernia. Observations on the absorption of fat from the middle of the ileum in this patient showed the following facts. In a human being the ileum secretes a fluid which contains about 2 per cent of lipids. The

presence of bile acids increases the volume of the secretion, while its lipid concentration remains unchanged. Olive oil and oleic acid are absorbed from the ileum even in the absence of bile acids. Bile acids in small amounts have apparently no effect on the rate of absorption of fats from the ileum. Large amounts of deoxycholic acid increase the volume of the excretion and so tend to reduce the rate of absorption of fat.

The Adrenal Gland—Broster discusses a series of twenty-three cases of virilism in which unilateral adrenalectomy was performed without a fatality. A specific differential staining reaction has been found in the cells of the adrenal cortex, which is absent in controls. It is also present in the tumor cells in cases of virilism due to neoplasm. This stain has been verified and its presence shown in the opposite adrenal at necropsy by others. This stain is present in the fetus of both sexes, and virilism can be explained by its abnormal persistence in the female. In some of the patients an increased amount of cholesterol was observed in the blood. The author cannot say what the significance of this stain is. It is associated with definite changes in the growth and development of the body tissues which have reverted to normal after unilateral adrenalectomy. In some cases it has been associated with alterations in the psychologic outlook of the patient which have reverted to normal after operation. The same changes have been observed in arrhenoblastoma of the ovary. From an examination of more than sixty cases of virilism of varying degree it is concluded that heredity plays a part. A family history of hirsutism was present in 25 per cent, and in these it was twice as common on the distal side. There is slight evidence that it is associated with the events which occur at birth. It occurred in two cases of twin births and in one case of premature birth, and in one case it appeared in the 4 year old daughter within three months of its onset in the mother. It appeared in several persons whose mothers suffered from exophthalmic goiter and in one whose mother suffered from diabetes. Women with virilism are comparatively infertile. If they conceive, they are

apt to miscarry. On the other side, one patient on whom unilateral adrenalectomy had been performed and who suffered from amenorrhea has since married and produced a son.

Effect of Anesthetics on Lymphatic Absorption in Peritonitis—Since many patients with spreading peritonitis complicating acute perforative appendicitis are operated on, either inadvertently or designedly, during the early stages of the disease, Mengle wished to ascertain, if possible, what effect was exerted by the anesthetic on the rate of lymphatic absorption. His experiments were performed in normal animals, animals with local peritonitis, animals with spreading peritonitis of a duration of twenty-four hours and animals with spreading peritonitis of a duration of forty-eight hours. The results show that in normal animals and those with either local or spreading peritonitis the greatest stimulation to lymphatic absorption (and so to toxic absorption) is produced by the anesthetics which most stimulated the activity of the diaphragm. It is believed, therefore, that local infiltration or regional block anesthesia with 1 per cent procaine hydrochloride or low spinal anesthesia with procaine hydrochloride is the method of choice for operations in the presence of peritonitis.

Pruritus Ani—There is nothing in Tucker and Hellwig's observations that would suggest a bacterial or parasitic cause of pruritus ani. Certain bacteria or fungi may complicate pruritus, but in the early stages in their cases no histologic evidence of bacterial or parasitic infection was present. The results of their microscopic examinations were not in harmony with the theory that pruritus is an allergic disease, and the neurogenic theory of pruritus also seems unwarranted. They disagree with those who believe that inflammatory lesions of the anal canal and hemorrhoids are responsible for pruritus. There was no difference between the pathologic picture of the anal canals of persons with pruritus and of persons without pruritus. The four stages which they have seen in pruritus—exudative inflammation, epidermoid proliferation, atrophy of the epidermis and sebaceous glands and epithelial defects—can be produced in the skin of rabbits and mice by certain chemical substances which, in various pathologic conditions, are present in the human feces. Besides other hydrocarbons, skatole may be the responsible agent. Stoerber and Wacker were able, by the injection of skatole into the rabbit, to produce the same cutaneous changes which have been described in pruritus. While skatole is absent in the stool of healthy children and also in the stool of most adults, Herter found excessive amounts in the feces of patients suffering from mental depression and anemia and especially from chronic intestinal disorders. These conditions are, according to Montague, often associated with pruritus. In healthy children, on the other hand, true pruritus is unknown.

Raw Apple Dietary in Treatment of Diarrhea Melena Neonatorum—Corcoran treated a case of melena neonatorum complicated by diarrhea with raw apple feeding to control.

diarrhea. This dietary was used on the third day of life. The sequence of symptoms and clinical course in this case closely followed repetitious descriptions of symptomatic melena vera. There were no prodromal symptoms preceding hemorrhage. An insignificant change in the number of erythrocytes following the first blood count is sufficient reason for assuming that hemorrhage in this patient was not adversely affected by the method of feeding. On the other hand, there is insufficient reason for assuming that the period of hemorrhage was shortened since hemorrhage, in those cases of melena which recover, may be expected to stop spontaneously, usually between the second and fifth days. That diarrhea was a more alarming factor than hemorrhage became evident after the second red blood cell count, but there was encouragement as well as surprise in the pure culture of bacillus coli. It is difficult to account for the loss of only 100 Gm in body weight during seventy-two hours of apple feeding unless one assumes that, besides the absorbent and detoxifying properties generally attributed to it, apple pulp possesses the additional property of promoting retention of fluids. The infant received only 47.5 calories during the first twenty-four hours, 67.5 calories in the second twenty-four hours, and with the addition of 5 per cent lactose, 229.5 calories during the third day. And yet, despite the fact that diarrhea was severe, there was negligible loss of weight and no appreciable decrease of tissue turgor.

Studies on Mechanism of Diuresis—Herrmann and Decherd compared the diuretic effect of mercupurin, mersalyl and mercurin suppositories. Their data concern results in seventy subjects with edema who have been observed under standard conditions of a preliminary rest in bed of from three to five days, on a constant intake of 1,600 cc of fluid and a low protein salt poor diet. Only five suffered primarily from the effects of cirrhosis of the liver, the others presented evidences of organic heart disease of one type or another with congestive failure in various stages and of varying degrees. To these seventy patients, 200 injections of mercupurin were given intravenously and alternately, for comparison, 115 injections of mersalyl were given in 2 cc doses of each, and sixty-four mercurin suppositories were administered. Taking all the results as they came, the conditions of course varying, now in favor of one drug and now in favor of the other, it seemed that mercupurin was favored. The average responses for the first, second

and third days following administration of mercupurin showed increases of 430, 92 and 91 per cent respectively, while for mersalyl the averages during the same period showed 293, 92 and 42 per cent. A secondary rise after the first day was occasionally noted following mercupurin. Both mercurial diuretics accomplish a maximal effect within the first day, the two drop about equally during the second day, but there was often persistence of the effects during the third day after mercupurin, while the mersalyl diuretic effect dropped considerably on the third day. The mercurin suppositories showed a 264 per cent increase for the first day, 66 per cent during the second and 25 per cent during the third day, a threefold augmentation of urinary output when the enema was used to prepare the intestine. The diuretic effects did not persist as actively as after intravenous use. Preliminary oral administration of xanthines and of acid salts likewise distinctly augmented the diuresis that resulted from mercurin suppositories.

Relation of Rickets to Anemia—McDonough and Borgen observed thirty infants and children, ranging in age from 6 months to 3 years, who were admitted to the State of Wisconsin General Hospital with a diagnosis of active rickets. Of those suffering from mild to severe acute rickets, sixteen, or 53 per cent, had normal hemoglobin readings and red blood cell counts. Fourteen, or 47 per cent, had readings of 60 per cent hemoglobin or lower. Eight of the cases showing low hemoglobin readings were complicated by dietary deficiencies or infections. Eleven cases in the entire group were complicated by dietary deficiencies, infections or anomalies such as cleft palate. Eight of the eleven complicated cases showed anemia, whereas only six of the nineteen uncomplicated cases showed a reduction in hemoglobin. In an attempt to throw some light on the relationship of anemia to rickets, severe rickets was produced in the chick and a comparison of the hemoglobin content of the blood of the rachitic with that of the normal chick was made. No significant difference in the hemoglobin content of the blood of normal and rachitic chicks could be demonstrated. Analyses of the livers of normal and rachitic chicks revealed no significant difference in the total and available iron content. In the rachitic chick, the abnormal calcium and phosphorus metabolism had no effect on the absorption and storage of iron so far as could be demonstrated. From the clinical evidence and the experimental results with the chick, it may be concluded that anemia is not a symptom of rickets but is probably secondary, in the infant, to complicating factors such as nutritional deficiency or infections.

Amicrobic Pyuria—Wildbolz points out that amicrobic pyuria is easily curable by medication but is often mistaken for tuberculosis of the urinary tract. As a result of such mistakes, nephrectomy has been performed unnecessarily on a number of individuals. Soderlund and Runeberg showed that there are two kinds of amicrobic, nontuberculous pyuria: a terminal stage of a urinary infection primarily caused by *Bacterium coli*, staphylococci, streptococci and the like and a primary amicrobic pyuria. The origin of the first form of sterile pyuria may be understood by comparison with similar processes elsewhere. The pathogenesis of primary amicrobic pyuria is not yet clear. No bacteria have been found in the purulent sediment by microscope or culture. This primary amicrobic pyuria usually sets in acutely with marked symptoms of the bladder, urgency, tenesmus and painful micturition. There is no fever and no constitutional disturbance. The urine is purulent and generally contains red blood cells. Sometimes there is sufficient blood in the urine to be noticed by the patient as terminal hematuria. Cystoscopy shows the bladder mucosa reddened in patches with ecchymoses and mucus in the form of stripes or round white necrotic membranes. There is pus in the urine from one or both kidneys on ureteral catheterization. In spite of this renal pyuria a marked decrease in kidney function has not ensued. This amicrobic pyuria is observed only in young men, very rarely in women. Only Schaffhauser has succeeded, in a few cases of typical amicrobic pyuria, in growing a nonhemolytic streptococcus on Rosenow's bouillon; cultures were positive on this medium alone. The clinical course, the anatomic observations and the first positive inoculations on animals make it probable that the so-called amicrobic pyuria is caused by an infecting agent as yet unknown. Therapeutic experience seems to confirm this view. Amicrobic pyuria has been cured promptly by one or two 0.15 Gm intravenous injections of arsphenamine preparations, even when the patient

has suffered from pyuria for months and years which has resisted all other therapeutic efforts. The author sometimes uses these injections as a quick means of differential diagnosis in cases in which microscopic and cystoscopic studies do not reveal at once whether he is dealing with a tuberculous or a so-called amicrobic pyuria. He has observed twenty-one patients with amicrobic pyuria. Six were cured in a short time by bladder washes, and in fifteen arsphenamine therapy effected a prompt cure.

Racial Incidence of Urolithiasis—Cary shows that figures of other investigators do not agree with the comparatively frequent cases of urolithiasis occurring in St. Philip's Hospital for Negroes, a unit of the Medical College of Virginia, in Richmond. His figures along with those from other institutions in the same region for five years (from 1931 to 1935) indicate that cases of urolithiasis are from three and one-half to five times as frequent among white persons as among Negroes. Although a mixed blood may increase the number of cases among Negroes and thus decrease the difference between the races, neither the admissions nor the population ratios rise to the extent expected from the reference in the literature to the "rarity" of Negro incidence of urolithiasis.

Neurologic Complications After Vaccines and Serums—Robinson discusses the occurrence of a case of flaccid peripheral nerve paralysis following the prophylactic administration of typhoid-paratyphoid A and B vaccine. Its recognition led to a consideration of similar neurologic complications which are occasionally encountered in the administration of serum antitoxins and vaccines. A careful elimination was made of other possible causes for this paralysis, which occurred four days after the second injection of the vaccine. At this time there occurred left foot drop, followed later by atrophy and reaction of degeneration. Physical therapy was administered and three and a half months after the onset recovery was practically complete and improvement was still progressing. The differential diagnosis demands distinction from peripheral paralyzes caused by anterior poliomyelitis, lead poisoning, diabetes, alcoholism and avitaminosis. In commenting on possible etiologic mechanisms, a consideration has been given to triphenolic compound so frequently used as a preservative in serums and vaccines. In this connection there is presented the

evidence which incriminates triorthocresyl phosphate as the cause of peripheral neurologic involvement in apiol and jamaica ginger poisoning. The similarity in both symptomatology and pathologic manifestations in these cases, in cases following serums and vaccines and in a reported case following experimental phenol poisoning in a monkey is pointed out.

Intrapartum Care in Relation to Maternal Welfare Maternal Welfare Article Number Fifteen P T Williams Philadelphia—p 330

Prognosis in Regional Ileitis—Crohn states that in the acute type of ileitis the prognosis is altered by the severity and the rapidity of the course of the disease. Palliative attempts at drainage, appendectomy or skilful neglect seem useless. Many surgeons have attempted to relieve or cure the disease by anastomosing proximal healthy ileum to healthy colon, thus short-circuiting the lesion and rerouting the intestinal content over normal mucosa. It appears that palliation is not only futile but in addition increases the risk of subsequent operation. That short-circuiting frequently fails, there is no doubt, that it may also at times suffice to cure must remain an open question for the time. Seventeen cases of ileitis in which no direct operative intervention had been practiced are now under observation (from one to three years). Three patients died of peritonitis and exhaustion. In another patient not operated on the ileum had to be resected after two years because of a rapidly downhill course with fever, diarrhea, mass formation and obstruction. Four of these patients without operation are seemingly doing well, gaining slightly in weight and showing an occasional slight tendency to diarrhea but no real abdominal distress and no loss of efficiency. The author believes that in these patients fistulas will eventually form, or obstruction may take place, though it may take years. And yet, scientific precision and clear thinking require one to maintain the premise that a complete restoration ad integrum is within the possibilities of nature. Another four patients are obviously not improving, the symptoms of mild bouts of diarrhea and cramps continue, associated with fluctuating slight loss or slight gain of weight. The remaining patients are lost to the present follow up. In short, in the best of hands the prognosis is excellent when a radical resection is performed. Palliative short-circuiting procedures as well as skilful neglect and so-called conservative medical treatment, are still on trial, and the prognosis is still to be determined.

Prevention of Congenital Syphilis—Hogan points out that the consensus is that congenital syphilis can be prevented with adequate treatment before the fifth month of pregnancy in the vast majority of cases. This has been proved beyond all question of doubt. No physician should withhold anti-syphilitic treatment from a syphilitic pregnant woman, even if asymptomatic, for should the child develop manifestations of the disease it would be difficult to accept such a grave responsibility. Every family physician and antepartum clinician should never neglect to take a careful history and physical examination, including a Wassermann test, on all pregnant women before the fifth month of gestation. Every syphilitic woman in the child bearing period should be considered as having potential possibilities of transmitting the disease to her offspring and the required therapy should be instituted at the first sign of pregnancy, regardless of the Wassermann reaction, previous treatments and symptoms.

Infections of Fingers and Palm—Koch points out that accurate diagnosis of infections of the fingers and palm involves first of all a diagnosis as to the exact location and extent of the infection. Infections of the hair follicle, paronychia, subcuticular infections, felon collar-button abscess, subfascial infections, joint infections due to small penetrating wounds and spreading lymphangitis are all distinct and definite entities whose differences depend primarily on the anatomic conformation of the part of the hand involved. Failure to keep in mind exact and essential anatomic facts leads to mistaken diagnoses and, as an inevitable corollary, to failure in surgical treatment. In preparing the field of operation there is nothing more effective than soap and water to cleanse the skin and to get rid of desquamating epithelium and coagulated wound secretion. A general anesthetic is always to be preferred to a local or freezing procedure. The great advantage of a bloodless field, easily obtained with the help of a blood pressure apparatus, should always be kept in mind. The use of drainage material which favors and does not prevent escape of wound secretion and which can be removed with a minimum of discomfort to the patient deserves consideration. When the drain is removed at the end of from twenty-four or forty-eight hours it should not be replaced. There is no more certain way of adding further infection to the open wound than by the repeated insertion of drains. If the original incision is adequate and correctly placed reinsertion of a drain should not be necessary. After operation for infection a large dressing to enclose the entire hand and forearm should be applied if the infection is more than a paronychia, and the entire upper extremity should be dressed if there is evidence of rapid extension. Except for the occasional addition of small amounts of the sterile solution, the dressing is left undisturbed for twenty-four hours. The importance of conserving function should be kept in mind from the outset of treatment.

Sterilization of Air in Operating Room—Hart points out that the air in any closed space, as in an operating room occupied by human beings, is highly contaminated with pathogenic bacteria. The usual operating room mask is inadequate. A protection was devised for the operating room personnel consisting of a hood of starched cloth over the head, face and neck with goggles of plain glass to protect the eyes. It was necessary to maintain suction beneath the goggles to prevent fogging. The gown and gloves apparently give sufficient protection to the skin that is covered. The author found that bactericidal radiant energy (supplied by an ultraviolet radiation apparatus) is almost 100 per cent efficient in killing the organisms floating in the air in the operative field at a distance of 5 feet from the source of radiation, while it is 80 per cent efficient at distances of from 8 to 10 feet. This radiation will not blister a blond at 5 feet within eighty minutes, in a series of more than 200 operations, no patient has been burned, and there has been no demonstrable damage to the tissue exposed in the wound. With adequate protection, no member of the operating room personnel has received a burn. By the use of this radiant energy, operating room infections have been greatly reduced, the postoperative temperature in supposedly clean cases has been lower and of shorter duration, there has been better healing, and the patient has had less postoperative discomfort. It is the author's opinion that, without bactericidal radiant energy to sterilize the air, every wound is highly contaminated with pathogenic bacteria.

Fetal Postural Mechanism—Rudolph compares the position of the fetus in the case reported with the position of the fetus of the lower animals (rodentia to monkey). Throughout pregnancy and within about three hours of the delivery the presenting part was not in contact with the bony pelvis, the inclined planes or the pelvic floor. The roentgenograms demonstrated the rotation of the fetus on its longitudinal axis from an anterior to a posterior occupant position and from a posterior

to an anterior vertex position with the fetus in utero. The roentgenograms throughout pregnancy and labor, to within about four hours preceding delivery, demonstrated that the angle between the longitudinal fetal axis and the pelvic inlet was approximately 60 degrees. The fetal head was noted constantly during pregnancy and part of the labor to be in a state of partial flexion, the flexion not being dependent on the resistance of the pelvic cavity. In spite of the position of the uterus, there was a normal delivery. The mechanism of labor in this case is ascribed to a phylogenetic process. Hypothetically, if the patient is considered in a pronograde position, one can correlate the mechanism of labor to that of the lower animals, bearing in mind that the change in the various movements is dependent on its phylogenetic function. From the x-ray study of the fetal posture during pregnancy and labor and the behavior of the uterus evidenced by the normal spontaneous delivery of the fetus, the author is led to the conclusion that the fetus has a definite fetal postural mechanism to account for its maintenance of a specific attitude.

- Resection of Carcinomatous Rectosigmoid with Bowel Continuity Reestablished Preliminary Report H R Arnold San Francisco—p 282

Trichomonas Infestation of the Bladder—During the last two years Nitschke has examined by means of the cystoscope thirteen patients with trichomonas vaginitis who were referred to him because of urinary symptoms. The usual symptoms were frequency, burning on urination, dull pain above the symphysis pubis, pyuria and, in one instance, hematuria. A distinction should be made between changes of the bladder observed when *Trichomonas vaginalis* is found in the urine and those when the parasite is absent. Therefore he considers each group separately. In his series of fifteen bladder observations, no typical change was noted. The cases in which *Trichomonas vaginalis* was present in the urine showed a wide variation in the cystoscopic picture. In two instances there was reddening of the entire bladder mucosa. In the nine instances in which the parasite was absent from the urine, the cystoscopic picture of the bladder did not materially differ from that usually seen in ordinary bacterial cystitis. They varied from a slight amount of edema in the region of the neck of the bladder with some blurring of the vessel outlines of the trigon to a moderate amount of edema of the neck with some swelling of the mucous membrane and increased redness of the lower half. The author believes that the infection invades the bladder through the urethra. Cystoscopically, changes have been observed involving the entire bladder mucosa, which seemed of a superficial nature. These observations would lead one to suspect the urethra as the avenue of infection rather than any deeply placed lymphatic or vascular channel. *Trichomonas vaginalis* has been found to occur in the urine associated with such bacteria as streptococci, staphylococci and *Bacillus coli*. The cystitis often associated with trichomonas vaginitis may be due to any one of a number of organisms or to a mixed infection.

*Plasma Phosphatase and Phosphorus During Healing of Fractures in Children Olive D Peden—p 87
*Iron Deficiency Anemia of Late Infancy H W Fullerton—p 91
Delinquency in Relation to Broken Home R G Gordon—p 111

Plasma Phosphatase and Phosphorus in Fractures—Peden investigated whether a greater rise in the plasma phosphatase content after an injury to bone could be demonstrated in children, in whom the bone-forming mechanism is much more active than in adults. The ages of the patients ranged from 5 to 12 years. The phosphatase content of the plasma and the inorganic phosphorus and the calcium content of the serum were determined in sixty-two cases. The method adopted for the estimation of phosphatase was that of Jenner and Kay. The plasma phosphatase appeared to increase within the first few days and thereafter to decrease. The serum phosphorus reached a maximum at the end of the first week. The serum calcium was not significantly altered. The change in plasma phosphatase was most marked in cases of fracture of the femur.

Iron Deficiency Anemia of Late Infancy—Fullerton discusses the etiology of the iron deficiency anemia of late infancy (from 9 months to 2 years) under four headings: the type of milk feeding, the effect of maternal iron deficiency, the birth weight and the influence of infections. Although reliable data are insufficient for definite conclusions to be drawn, the greater degree of anemia present in artificially fed infants is probably due to a low retention of iron. This theory does not explain the fact that in Mackay's series the artificially fed infants showed lower hemoglobin levels than the breast-fed infants at all ages from birth to 13 months. In the absence of increased loss of iron from the body, iron deficiency does not occur in infants of average birth weight in the early months. Only from the fifth month onward is there a consistent difference in the hemoglobin levels of breast-fed and artificially fed infants. The results obtained in sixty-five infants within twenty-four hours of birth and in forty-seven infants on the eighth day support the conclusion that maternal anemia does not influence the hemoglobin level of the infant at birth. From the average hemoglobin levels of 222 infants from 9 to 23 months of age it is seen that the lower the birth weight the lower the hemoglobin level in late infancy. The smaller the infant at birth, the lower the absolute iron content of circulating hemoglobin. Consequently, less iron is conserved after post-natal hemolysis, to be utilized in the new formation of hemoglobin that accompanies growth. The common infective illnesses of infancy produce a rapid fall in the hemoglobin level and may inhibit regeneration of the blood for a considerable time after the disappearance of clinical evidence of infection.

Musicogenic Epilepsy—Critchley describes the occurrence of epileptiform attacks in factual association with the hearing of music. He cites four personally observed cases and seven

cases seen by colleagues. Cases of this phenomena are too rare to permit dogmatic conclusions as to the clinical features which may be regarded as characteristic. From such evidence as is available, however, it appears that the association between stimulus and attack is a close one, only rarely does a seizure occur without the precipitating factor of music. On the other hand, music may be heard without an epileptic attack necessarily following. There is reason to believe that in some cases only certain types of music may be followed by unconsciousness. An attack does not usually follow promptly the onset of the music, and the stimulus may need to be maintained for many minutes before producing a fit. The character of the epileptic phenomena proper varies from transient "absences," or obfuscations of consciousness, to complete major attacks with convulsive movements and vesical incontinence.

*Investigation into Risks of Fire or Explosion in Operating Theaters J H Coste and C A Chaplin—p 115
Analgesia for Labor Pains Duration of Labor Pains Hilda Barry—p 132

Explosions in Operating Theaters—Coste and Chaplin declare that ethyl chloride yields a vapor which forms an explosive mixture with air and its use is dangerous in proximity to flames or apparatus likely to yield a spark or hot wires. Ether or mixtures of ether with chloroform, or alcohol and chloroform vapor and oxygen, or nitrous oxide obtained in and delivered from ether saturators of the usual type are likely to be explosive, either alone or when they become diluted with air, and present dangers when in proximity to flames or apparatus that may yield a spark. The danger of explosion or burning with open mask ether anesthesia is small, owing to the rapid descent of ether vapor through air. Explosions due to dangerous concentrations of ether vapor in the air of an operating room, even after the accidental breaking of a bottle of ether, are most unlikely if the possible source of ignition is a foot or more above the floor level and not directly under the liquid ether spread on the mask or other surface.

*The Heart in Pulmonary Tuberculosis A Hope Gosse and A Wingfield—p 92

The Heart in Pulmonary Tuberculosis—From a study of the physiologic data Gosse and Wingfield conclude that there is no one factor affecting the cardiac function in pulmonary tuberculosis which can be effectively initiated experimentally, and attention must therefore be paid to the actual observations in patients suffering from the disease. From a review of the literature no conclusive results have been obtained. The cases reported are divided into two groups. The first consists of forty-seven cases in which no collapse therapy had been undertaken and in which no major pulmonary complication was detected. In the second group of fifteen are found cases in which some form of collapse therapy had been employed. Of the forty-seven cases, twenty-three showed no deviation from normal, while twenty-four are thought to show some electrocardiographic abnormality. The majority of the patients (74 per cent) were less than 35 years of age. Of the twenty-four cases in which the electrocardiogram deviated from the normal, right and left axis deviation was observed in five cases each, a low

potential in only lead 1 was present in ten cases, in lead 3 in two cases, in leads 1 and 3 in one case, and in one case an inverted T wave was recorded in leads 2 and 3. Of the cases showing normal electrocardiograms, cardiac displacement was present in seven, while in sixteen the heart was normally placed. A systolic blood pressure below 110 mm of mercury was recorded in eight cases, only two of which showed a cardiac displacement, while two others were regarded as having very active disease. As a result of their investigations the statement that a low blood pressure is a significant feature of pulmonary tuberculosis is not acceptable to the authors. In no case was the transverse diameter of the heart greater than 6 inches (15 cm) in a teleroentgenogram, and the cardiothoracic index was in each case less than 50 per cent. They have not been able to gain any assistance from detailed examination of the cardiovascular system which would help them in the prognosis or the treatment of pulmonary tuberculosis. Among four cases treated by artificial pneumothorax, right pneumothorax was present in three, showing, respectively, left axis deviation, right axis deviation and a low potential in lead 1. The fourth case with a left-sided artificial pneumothorax showed a low potential in lead 3 and a low systolic blood pressure. Phrenic avulsion was carried out in four cases, two showed a systolic blood pressure below 110 mm of mercury. The two cases showing low potentials in lead 3 also showed, roentgenographically, displacement of the heart to the right. Seven patients were examined electrocardiographically in only one case did the character of the record change materially, and in this case right axis deviation disappeared and a low potential in lead 1 was recorded subsequently. A systolic blood pressure of 96 was recorded in one case. In two further cases right and left axis deviation, respectively, were recorded and remained unchanged after operation.

Atropine Dosage in Chronic Epidemic Encephalitis—Hall followed the treatment recommended by Kleemann in some of his fifty-eight cases of chronic epidemic encephalitis. Kleemann begins with 0.5 mg of atropine daily in the form of 0.5 per cent solution of atropine sulfate given in two doses. This is increased by 0.5 mg daily, spread over three doses and given so long as any objective or subjective improvement is produced (maximal dose). When this point is reached reduction should be gradual in order that the optimal dose on which improvement is maintained may be fixed. After an initial small dose was tolerated, the author made a greater daily increase without ill effects in some cases. Indeed, to patients who have previously been for some time on tincture of belladonna one may give 5 or even 10 mg of atropine on the first day and increase the dose by 2.5 mg daily not only without ill effects but in suitable cases with rapid benefit. Earlier observers emphasized the necessity of keeping the patient in bed while one is estimating the optimal dose. In the author's experience, unless the patient is already bedridden, complete rest is neither necessary nor desirable after the first day or two of treatment. Even those bedridden at the onset are encouraged to get up as soon as they show signs of improvement. Close daily observation of the patient is essential so long as the dose is being increased. In Kleemann's cases the usual optimal dose was from 3 to 7 mg of atropine daily. In Hall's series the average optimal dose was about 18.5 mg daily. The greatest benefit is seen in cases in which the disability arises chiefly from muscular stiffness and excessive flow of saliva. Improvement may also occur in tremor, in the frequency of oculogyric attacks and in various spasmodic symptoms. In these, however, it is less in amount and more variable. Patients in whom psychotic disability is predominant and parkinsonism is either absent or

only slight do not usually show much benefit from this form of treatment. When the psychotic disability is largely secondary to the physical disability, removal of the latter by large doses of atropine may be accompanied by definite improvement in the former. Under no circumstances does the parkinsonian syndrome disappear completely, and unless the treatment is maintained and reinforced by suitable environment, the term being used in the widest sense, there is usually a rapid return to the pre-existing condition.

- Severe Rectal Injuries Caused by Enema Given Through a Rigid Nozzle W W Galbraith—p 859

Observations on the Dick Test—Ker finds that different Dick toxins can be satisfactorily matched only if the technique is carefully standardized, frequent readings are made and a considerable number of patients—probably fifty—are available. A properly stabilized dilution of Dick toxin when 6 weeks old apparently gives virtually as good reactions as when freshly made up. Dick control fluid should be heated for at least four hours. Pseudoreactors are rare but are encountered from time to time.

Treatment of Tetanus—Yodh investigated a series of 438 cases of tetanus, with special reference to the use of antitoxin. The combined method of administration of the antitoxin, intrathecal through the cisterna magna, intravenously and intramuscularly, was used in this as in a previous series. The total mortality for all consecutive patients except the fifteen that were discharged by request was 50.6 per cent, and after the patients that died within twenty-four hours of admission were excluded, 29.4 per cent. This compares somewhat unfavorably with the previous figures but may be explained by the fact that several brands of serums had to be used in these cases, while only one brand was used in the previously reported cases. The routine administration of paraldehyde by rectum is recommended in all cases as the most suitable sedative for hospital patients. The rapidity of the development of symptoms appears to be the important factor in prognosis. With a short incubation period, if the period of onset has been three days or more, there are many chances of recovery. The deep, penetrating injuries are more often followed by tetanus and have a high mortality. In 115 cases no injury or source of entry could be discovered. Either apparently trivial or unnoticed injuries may carry the infection, or the organisms present in the lumen of the intestine may become pathogenic. Fifty-six of the 115 patients showing no evidence of injury died.

Experiments on Neutralization of Hydrochloric Acid by Magnesium Trisilicate—Mann performed nine consecutive one hour test meals, both with and without the concurrent administration of magnesium trisilicate, on a patient with an

uncomplicated gastric ulcer The test meals showed that magnesium trisilicate is efficient in neutralizing the acid of the gastric contents Experiments are described that were designed to elucidate the relative importance of the phenomena of chemical reaction and of adsorption in the neutralization of hydrochloric acid by magnesium trisilicate These experiments showed that under certain conditions the amounts of acid "neutralized" by the two processes are in the approximate ratio of 7 to 2

Paroxysmal Tachycardia in Infants—In Campbell's series of 100 patients with paroxysmal tachycardia, four had a heart rate of 248, 240, 234 and 230, and the two that he cites had a rate of 300 and 274 The ages of the last two patients were 1 and 20 months In one the rhythm was characterized by auricular tachycardia or auricular flutter and in the other by ventricular tachycardia At present, after five and seven years, the hearts are normal and the outlook is as good as that for other children of their age, in spite of the serious heart attacks There is no evidence that they have, or have had, any structural heart disease and little, if any, that they had suffered from any infection which might have produced toxic myocarditis The author concludes that paroxysmal auricular flutter is much more frequent in infants than in adults, being more common than all the varieties of simple paroxysmal tachycardia combined and that paroxysmal tachycardia (of any variety) in infants is more likely to be associated with a diseased than with a healthy heart

Reinfection as Cause of Complications and Relapses in Scarlet Fever Wards—Allison and Brown observed patients with scarlet fever nursed in multiple bed wards as well as patients nursed in cubicles or single bedrooms They define the term reinfection as the secondary infection of a patient with scarlet fever during hospitalization with *Streptococcus pyogenes* belonging to a serologically different type from that producing the primary infection Of forty-seven patients with scarlet fever nursed in a multiple bed ward whose noses and throats were swabbed twice weekly during their period of isolation, thirty-three (70.2 per cent) became reinfected with a serologic type of *Streptococcus pyogenes* different from that causing the primary disease In fifteen of the thirty-three patients reinfected, the reinfection gave rise to no clinical signs, while in the remaining eighteen it was accompanied by clinical signs or complications Patients nursed in cubicles or in a ward confined to infections with a single serologic type did not show reinfection, their convalescence was progressive, and

there were no late complications The majority of complications occurring during the third week of hospitalization and subsequently in multiple bed wards devoted to scarlet fever are due to reinfection Most reinfections occur during the third week of hospitalization, at a time when patients are as a rule convalescent from their primary infection The most frequent mode of transmission of reinfection appears to be direct contact of patient with patient Ten instances of "relapse" in scarlet fever are cited in all of them the patients were nursed in multiple bed wards In each instance the "relapse" coincided with the isolation of a fresh serologic type of *Streptococcus pyogenes* from the throat and must therefore be regarded as a second attack of scarlet fever Patients with scarlet fever should be nursed in cubicles if possible Otherwise they should be nursed by the bed isolation method in multiple bed wards

The Genetics of Leukemia in Man—Ardashnikov undertook an investigation of thirty-three pedigrees, twenty-seven based on information supplied by patients and the others based on information supplied by the nearest relatives The cases discussed were collected systematically From an analysis of the familial cases a few new facts appear which argue against a contagious origin of leukemia The strongest objection to a hypothesis favoring common environmental influences (including infection) as causes of leukemia is the fact that there has been no recorded case of the disease in both husband and wife Thus, the familial cases described in his study together with the familial cases described in the literature—cases which cannot be explained as due to common environmental influences—favor the hypothesis that hereditary factors exert an influence in the etiology of leukemia The most probable explanation is a conditionally dominant autosomal type of inheritance, especially in the lymphatic form of leukemia, with great variation in the phenotype due to other genes or to external influences The existence of different forms of leukemia in the same family indicates the presence of some communality of etiologic factors in chronic myeloid and lymphatic leukemia

Vitamin B₁ and Fatty Livers—McHenry finds that the oral administration of vitamin B₁ to young rats maintained on a low choline diet causes an increase in liver fat A similar effect is produced in experiments in controlled feeding in which the appetite-stimulating effect of vitamin B₁ is avoided Young rats on a low choline diet without vitamin B₁ exhibit increased liver fat until their stores of vitamin B₁ are presumably exhausted Subsequently the liver fat diminishes It can be

kept at a high level by the administration of vitamin B₁. The amount of fat in the liver is increased by increasing the amount of fat in the diet, provided the diet is low in choline, but the liver fat, at all the levels of fat intake investigated, is increased by the ingestion of vitamin B₁. This is also the case when a fat-free, high carbohydrate diet is employed.

Fatality After Atabrine-Plasmochin—Decherd calls attention to the fact that when plasmochin and atabrine are given together the risk of toxic effects is clearly increased. In his case, 0.7 Gm of atabrine, given at the rate of 0.1 Gm three times a day, with 0.01 Gm of plasmochin a day for two days, was followed immediately by acute toxic hepatitis, which led to cholemia and death. It is, of course, difficult to say which drug caused the hepatic damage in this case, but it is certain that the combination was toxic. Permission for necropsy was refused.

Scurvy and Carditis—Taylor found that in guinea-pigs, in the absence of extraneous infection, scurvy leads to valvulitis and myocarditis with acute and subacute inflammatory foci. Gram-positive cocci or bacilli were present in half the diseased hearts, but many of the severest lesions showed no organisms. Scurvy with intradermal hemolytic streptococcus infection leads to cardiac lesions differing in no essential way, either in incidence or in microscopic appearance, from those seen in scorbutic guinea-pigs not so infected. Two thirds of the hearts showed organisms, and they were more numerous than in the scorbutic hearts—but one group of organisms was definitely not streptococci. The two animals that were scorbutic for the last seven of their eleven weeks showed enlarged hearts and congested livers. Intradermal hemolytic streptococcus infection in nonscorbutic guinea-pigs did not result in the characteristic cardiac lesions seen in scorbutic animals. Subacute scurvy with intradermal hemolytic streptococcus infection led to cardiac lesions similar to those seen in acutely scorbutic infected animals, but the hearts of these were large and the livers and lungs showed much venous congestion. The livers also showed fatty changes. Chronic congestive cardiac failure appears to have been produced. The one guinea-pig that spent the last five weeks of its life on an adequate diet showed no venous congestion, and, although there was no antemortem debility, its mitral valve contained organisms. A full antiscorbutic diet, started immediately after intradermal hemolytic streptococcus infection, did not cure the cardiac lesions. The full diet appeared to free the valves from organisms and to prevent the development of congestive failure. Scurvy with intradermal infection due to *Streptococcus viridans* resulted in cardiac lesions which did not differ from those seen in scorbutic guinea-pigs with or without extraneous hemolytic streptococcus infection. Two hearts showed organisms morphologically identical with those injected, but the second also showed diplococci with polar staining. Once again, subacute scurvy was associated with passive venous congestion.

Comparison of Punctate Basophilia and Ratio of Large to Small Lymphocytes in Diagnosis and Prevention of Lead Poisoning D O Shields—p 535

Signs and Symptoms of *Taenia Saginata* Infestation.

—Penfold discusses the signs and symptoms of 100 consecutive patients who together harbored a total of 219 specimens of *Taenia saginata*. Only two patients did not notice segments in their stools. These two cases in no way indicate that patients may harbor mature worms without detached segments being expelled in the feces. Seven patients during the course of their infestation did not notice segments on their underclothing and were not aware of segments crawling through the anus when defecation was not taking place. The ninety-three patients who complained of detached segments crawling through the anus gave varied accounts of the frequency of this occurrence. Only two of the 100 patients vomited segments, one after a general anesthetic and the other during the course of pneumonia. Abdominal symptoms were almost always referable to the epigastrium. Occasionally pain was complained of in the hypochondria, in the lumbar region or in the lower part of the abdomen. The types of pain varied greatly. The nature of the digestive disturbances other than pain was also variable. Among the complaints were sinking, hungry feeling, distention, vague discomfort, heavy feeling, gnawing sensation, empty feeling, appreciation of worm movements, flatulence, water brash and nausea. At least four patients had the typical duodenal ulcer sequence of pain, food, comfort, pain. Giddiness was complained of by thirty-seven patients. The majority of these noticed it when they were hungry through being late for meals. Others noticed that giddiness was induced by stooping, running, much standing or walking, or on first getting up in the morning. Of the seven patients whose appetite was increased, only two ate noticeably larger meals when infested. No evidence was found to suggest that the patient's weight was reduced directly by *Taenia saginata* infestation. Neither constipation nor diarrhea was a significant symptom. Apart from the anal irritation experienced while segments were actively crawling through the anus, pruritus was complained of by only two patients, in neither was it very troublesome. Lassitude was distinctly noticeable in four cases. Nasal pruritus and salivation did not occur in any case. Headache appeared to be caused by the infestation in only one case. Vague aches were complained of by several but may not have been caused by the parasites. None of the patients, after expulsion of the adult parasite, had any signs or symptoms suggestive of cysticercosis. Twenty consecutive cases of *Taenia saginata* infestation were examined hematologically, sixteen showed a relative lymphocytosis varying from 33 to 59 per cent. Only two of the twenty patients had an eosinophilia. The eosinophil cells represented 13 per cent of the white cells in one case and only 6 per cent in the second.

- *Septal Infarct with Protracted Fever C Laubry and P Soulie — p 183
Propagation of Contracting Wave into Ventricle of Frog R Lutembacher — p 191
New Aspects of Auricular Pathology Partial Fibrillation and Flutter Olyntho de Castro — p 207

Septal Infarct with Protracted Fever—Laubry and Soulie report a variety of septic infarct with coronary thrombosis and protracted hyperpyretic state which brought about profound changes in the ventricular walls. The condition is characterized by three clinical aspects: 1 The temperature has been around 104 F for more than six months, which is unusual in coronary inflammations, especially when no infection, not even a focal infection, could be demonstrated. The authors hold that the progressive parietal atrophy is due to the transformation and absorption of large quantities of albumin, however, this cannot be held responsible for such a high and prolonged hyperpyrexia. 2 There is total absence of pain, which theoretically should be caused by the changes in the ventricular wall. The intense ischemia which produced advanced myocardial atrophy, the profound vascular lesions and the pericoronary sympathetic alterations are factors which made the absence of pain possible. 3 While generally an infarct of the lower septum is accompanied by characteristic changes in the electrocardiogram, this case showed no changes in the ventricular complex in spite of the massive alteration of the ventricular wall. Furthermore, in this case the circular necrotic area affected merely part of the wall without causing perforation. If the observed changes assume the histologic aspect of a parietal aneurysm, it is the result of two distinct lesions: a violent necrotic process and a nutritional deficiency. There were no pericardial or symphyseal reactions.

*Lipidose Research in Neuropathology II Cerebroside Lipidoses L Van Bogaert — p 698
Practical and Economic Advantage of Systematic Pulmonary Examinations Prophylactic Antituberculous Measure P Braun — p 701

Lipidose Research in Neuropathology—Van Bogaert emphasizes the complexity existing in the relations between neuropathology and the various lipidoses. Yet, today it is possible to classify the diseases of lipid-metabolic origin into three principal groups. Characteristic of these groups is the presence of deposits of complex lipoids and of fatty substances in different parts of the organism. Each group is further characterized by the quantitative predominance of a particular lipid in the deposit. The first group is that of cerebroside lipidoses (Gaucher's type), distinguished by a substance known as kersan. In its cerebral form it manifests itself as the pseudobulbar type of Gaucher's disease of infants. It is marked by swelling of the cells and a poorly staining granular substance. The neurofibrils are dislocated and the dendrites swollen. The second group, that of phosphatide lipidoses of the Niemann-Pick type, which is much less limited than the preceding group, is distinguished by the presence of phosphatides of the lecithine and sphingomyelin groups. This group is known for its cerebral manifestations, and a large number of amaurotic idiocies may belong to it. The third group, observed by Schuller-Christian, is that of cholesterol lipidoses in which there is generalized and typical xanthomatosis of the skin and tendons. It is distinguished by the presence of cholesterol and its esters.

- *Experimental Venous Obliterations and Resections Contributions to Study of Venous Collateral Circulation R Fontaine and S Pereira — p 161
Hernia Through the Semilunar Spigelian Line G Bachy — p 201
Surgical Form of Tuberculosis of Penis J Brunati — p 213

Experimental Venous Obliterations and Resections—Fontaine and Pereira have conducted a number of experiments on dogs blocking the venous backflow and observing the resulting edema. They practiced either resection of veins or chemical thrombolysis with from 20 to 30 per cent of sodium

salicylate or 100 per cent of sodium iodide, or finished the resection with a chemical obliteration. They noticed no difference between the surgical and the chemical intervention. After each operation they made a minute record of all the changes in volume and made phlebograms at stated intervals after injecting a solution of thorium dioxide into a tarsal vein. The first series of observations revealed that resection and obliteration of the superficial femoral vein has no particular circulatory consequences. The same operation performed on the entire femoral and saphenous veins results in temporary blockage of circulation manifested by a short-lived edema. The latter is prolonged by ligating all cutaneous and large muscular veins of the thigh. Simple ligation of the femoral vein at its junction with the inferior vena cava originated an edema lasting twenty-four hours, but the traumatization of the femoral vein resulted in an edema of several days. In all cases the phlebograms explained the ease with which the circulation was reestablished by the abundant collaterals of the subcutaneous and muscular networks and their anastomoses with the abdominal wall and by the newly developing venous network in the internal aspect of the thigh. This takes place even if the entire femoral vein is suppressed. But when all veins are ligated at the proximal end of the thigh, moist gangrene of the limb supervenes with an enormous edema, to which the animal succumbs. Lastly, experiments were made on the lymphatics which were visualized by an injection of thorium dioxide. The left ilio-lumbar vessels were resected and an injection of 5 cc of a 30 per cent sodium salicylate solution was given in the two lymphatic vessels of the tarsus. The edema thus provoked lasted eight or nine days. When, however, all the veins were sclerosed from their origin down to the knee and the lymphatics resected, the animal died after forty-eight hours from a strong edema of the extremity. But the animal survived sclerosing of the veins and sclerosing and ligation of the lymphatics, the edema of the limb lasted twenty-five days. These experiments afford ample proof for the venospastic role in the pathogenesis of phlebotic edema in man.

*Quinine as Prophylactic Against Influenza O Spitta — p 452
Intoxication with Potassium Permanganate and Its Treatment C Strzyzowski — p 457

Roentgen Treatment of Phlebitis and Thrombophlebitis—Henschen and Becker review the literature and then state that their own observations on roentgen irradiation of phlebitis and thrombophlebitis were made in a small number of cases. However, the favorable results obtained in these cases induced them to continue the roentgen therapy on a larger material. The case histories indicate that from four to twelve irradiations effected disappearance of the phlebotic symptoms. Following a discussion of the diagnosis of the different causes of phlebitis and of various methods of treatment that have been recommended for phlebotic conditions, the authors discuss the mode of action of roentgen therapy. Among the general actions they mention increase in the bactericidal action of the blood, and stimulation of the formation of antibodies and of the reticulo-endothelial system. Local actions are, among others, production of local alkalosis, dilation of the capillaries, increase in the lymphatic circulation, and reduction of edema and pain. Moreover, the inflammation is lessened, certain bacteria are destroyed, phagocytosis is stimulated and the humoral and cellular actions are changed. One of the greatest advantages of roentgen irradiation is that it shortens the course of the phlebitis. Not only chronic and subacute, but also acute venous infections respond to roentgen therapy. It can be employed in the superficial, deep or mixed phlebotics of the legs and arms, but also in phlebitis of the pelvis, of the penis, of the mesentery and of the facial and cervical veins. Regarding the technic of irradiation the authors say that, the more severe the inflammation the weaker should be the irradiation.

tion As a rule the dose should be between 100 and 200 roentgens The doses should be increased or decreased according to the location and type of infection and the age and general condition of the patient

Quinine as Prophylactic Against Influenza—After pointing out that the use of quinine as a prophylactic against influenza was recommended already during the epidemic of 1889 and 1890, Spitta reviews the later literature and then discusses the dosage He recommends the use of quinine hydrochloride or quinine sulfate in quantities from 0.05 to 0.1 Gm a day He thinks that in most cases 0.05 Gm is sufficient but that at the peak of an influenza epidemic two such doses should be taken every day This amount of 0.1 Gm he recommends also for persons who are especially exposed, such as physicians and nurses

*Anemia in Leukemia L Beltrametti G Rettanni and A Bascapè—p 337
Chronic Erythremia Nosographic Classification B Nelli and O Benarolo—p 371

Treatment of Neutropenic Syndromes—Beltrametti says that the etiology and pathogenesis of agranulocytosis are unknown Consequently there are neither etiologic nor pathogenic treatments The most rational and useful treatments resorted to are transfusion, roentgen irradiations of the bones for direct stimulation of the bone marrow, administration of nucleic acid preparations and liver therapy All the treatments have a common mechanism of action by stimulating especially the granuloblastic tissue of the bone marrow The nucleotides contained in the blood and in liver extracts stimulate the myeloid tissues when transfusion or liver therapy is administered The roentgen irradiations result in destruction of the myeloid zones with consequent output of nucleotides, which stimulate granulopoiesis The treatment gives the best effects when it is administered early in the evolution of the disease, before the bone has suffered grave structural and functional lesions The author reports a case in which complete recovery followed repeated blood transfusion and the removal of carious teeth, which were causing focal infection

Anemia in Leukemia—Beltrametti and his collaborators studied the hemoglobin metabolism in twelve cases of myeloid and lymphatic leukemia with the purpose of finding out the pathogenesis of anemia (either hemolytic or due to defective regeneration of the erythrocytes by the bone marrow) in

leukemia They also followed the behavior of the erythrocytometric curves before and after treatment The latter consisted in roentgen irradiations of the spleen, the liver and the bones and blood transfusion Before the treatment there were hypoglobulia, hemoglobin values low in some cases and high in others, normal bilirubinemia and slightly increased reticulocytosis The average diameter of the erythrocytes was almost normal, but there was an increase in the numbers of erythrocytes with either larger or smaller volume than normal The metabolism of hemoglobin was increased in all cases After the treatment the blood crisis improved (there was an increase of the erythrocytes and decrease of the leukocytes), the metabolism of hemoglobin became normal or greatly diminished and the erythrocytometric curve decreased in amplitude and the volumetric variations were reduced The authors conclude that anemia in myeloid and lymphatic leukemia is due to hemolysis which originates in hyperfunction of the hemocathesis of the spleen According to the authors, roentgen irradiation controls hemocathesis with consequent control also of hemolysis and of anemia

Asymptomatic Neurosyphilis—Carrera and his collaborators studied the cerebrospinal fluid of syphilitic patients to ascertain the frequency of asymptomatic neurosyphilis The group included patients suffering from acquired and congenital syphilis in different stages of the disease, those who had and those who had not received antisyphilitic treatment Patients showing clear signs of neurosyphilis were excluded According to the authors asymptomatic neurosyphilis is rare, especially in congenital syphilis, in syphilis of long duration and in patients who have received treatment In the rare cases showing positive results for the tests of the cerebrospinal fluid for syphilis, the common antisyphilitic treatments cause normalization of the fluid with consequent negative results of the tests The administration of arsphenamine does not increase the probability of asymptomatic neurosyphilis developing More intense treatments, such as induced malaria, are indicated only if the common treatments, given for one or two years, fail to bring the results of the tests of the cerebrospinal fluid from

the pathologic to the normal figures. The only abnormality of the cerebrospinal fluid of three patients in the authors' group was to give positive results to the Wassermann reaction. The authors believe that the fact may be due to the presence of reagins in the body humors rather than to involvement of the nervous system by syphilis.

Does Pregnancy Last Longer Than Formerly?—Wahl says that measurements on more than 6,000 new-born infants, all of whom were of premature birth, revealed the length-weight quotient averages 515 cm 3,400 Gm. A comparison of these values with those formerly determined and accepted indicates that mature infants are longer as well as heavier than was formerly assumed. Regarding the duration of pregnancy, the author says that former studies in 4,000 cases, which have been corroborated by more recent studies in 5,000 cases, indicated that, counting from the last menstruation, pregnancy lasts from 284 to 285 days, that is, from four to five days longer than was formerly assumed. He suggests that the comparatively greater length and weight of the new-born infant is due to the fact that gestation lasts longer than formerly. He also discusses the length of pregnancy with regard to the date of conception, pointing out that, on the basis of his own observations and of the results obtained by Knaus, Ogino and others with regard to the term of ovulation, the average duration of pregnancy (counted from conception) is from 273 to 274 days. After directing attention to similar phenomena, such as the increase in the average height and in the life expectancy, the author cites several particularly social-economic environmental factors to which these changes may possibly be ascribed.

Epidemic Hepatitis P Selander—p 202

Bismuth Therapy of Tonsillitis During Childhood—Köhler states that a report by Vas de Mello on the effects of bismuth in the treatment of tonsillitis induced him to resort to this treatment for children with tonsillitis whose temperature rose above 38.5 C (101.3 F). The bismuth is administered by intramuscular injection in quantities of from 0.1 to 0.2 Gm. As a rule only one injection is necessary. Observations on sixty-one cases convinced the author that bismuth therapy effects a reduction in the period of fever. If the cases in which bismuth therapy was used were compared with cases in which it was not, the shortening of the period of fever in the former was the more noticeable the earlier the bismuth therapy was begun. It is advisable to administer the bismuth on the first or second day of acute tonsillitis. The author suggests that, even if the duration of the tonsillitis is not shortened, the bismuth therapy may prevent involvement of the middle ear.

Rhodium Compounds in Experimental Syphilis and Frambesia—Jahnel studied the action of simple rhodium compounds (sodium rhodium chloride and rhodium chloride) on spirochetes and on the symptoms of experimental syphilis and

frambesia in rabbits. The two rhodium preparations were administered chiefly by intramuscular injection. In experimenting with sodium rhodium chloride, the author found that, when 0.05 Gm per kilogram of rabbit was injected intramuscularly, the spirochetes disappeared from the syphilomas within twenty-four hours and the syphilomas healed rapidly without relapse. Smaller doses (from 0.01 to 0.02 Gm per kilogram) likewise exerted a therapeutic action, in that the spirochetes disappeared within twenty-four to forty-eight hours. In some of the animals relapses occurred after the small doses (0.01 and 0.02 Gm), but in others the same doses effected rapid cure without relapses. In one animal even 0.005 Gm per kilogram exerted a noticeable action on the spirochetes, but in another animal this dose was practically without effect. Frambesia reacted in the same manner as syphilis to 0.02 Gm per kilogram. The author also investigated the toxicity. He found that in case of intramuscular injection the therapeutic index is at least 1:2.5, in some of the animals it is between 1:6.25 and 1:12.5, and in extreme cases it was found to be 1:30. In case of intravenous injection 0.005 Gm per kilogram exerted a strong action on the spirochetes, these had disappeared within twenty-four hours. However, the tolerance for the preparation is considerably lower in intravenous than in intramuscular injection. Rhodium chloride is extremely toxic and exerts only a slight therapeutic effect in intravenous injection. To be sure, in the intramuscular mode of administration this preparation exerts a considerable therapeutic effect. The author says that for human subjects the use of rhodium salts is as yet inadvisable, because extensive clinical experiments will be required first. Aside from the fact that the two rhodium salts may cause local irritation in intramuscular injection, it will have to be determined whether other undesirable effects may develop. Moreover, other rhodium compounds should be studied for possible antisyphilitic action.

Copper for Reduction of Insulin Requirements—After calling attention to previously reported animal experiments on the action of copper on the carbohydrate metabolism, Schnetz describes his observations on human subjects. He administered copper sulfate in the form of pills, each having a copper content of 25 mg. Numerous preliminary experiments had revealed that from four to eight times this dose (from four to eight pills) is well tolerated as the daily dose. The author describes observations on normal subjects and on diabetic patients. He found that the normal blood sugar content is not noticeably influenced by the administration of copper, but that hyperglycemia, produced by epinephrine or by a dextrose tolerance test, is greatly inhibited by the action of copper. In diabetic patients it was observed that, when copper medication, in daily doses of from 10 to 20 mg, was continued for several weeks or months, there was a considerable improvement in the diabetic metabolism, which became manifest in (1) a reduction in the diabetic hyperglycemia and glycosuria, (2) a noticeable improvement in the general condition and (3) a considerable reduction in the insulin requirements, occasionally even with an increased carbohydrate intake. In patients with severe diabetes, the copper medication permitted a reduction of from 20 to 55 units of insulin in the daily dose, in patients in whom the diabetes was of moderate severity, up to 45 units of insulin could be saved each day, and in patients with the milder forms of diabetes the insulin therapy could be entirely replaced by medication with copper. However, whenever the treatment with copper was interrupted, the diabetic condition became once more exacerbated. Other advantages of the copper therapy were the more pleasant oral medication in the place of the repeated insulin injections and the lower costs.

*Cholesterol Metabolism in Multiple Sclerosis Charlotte Frisch—p 596

Biochemistry of Carcinoma B Lustig—p 598

Elimination of Prolan in Urine of Patients with Hypertrophy of Prostate O Wallis—p 599

Cholesterol Metabolism in Multiple Sclerosis—After pointing out that some authors regard multiple sclerosis as an infectious disease in which the causal agent is in the central

nervous system, Frisch suggests that the disorder in the central nervous system may be the manifestation of fermentative processes and their defense reactions. This would not even impair the theory of an infectious origin, in fact, it would suggest the possibility that the causal agent might be in a region other than the central nervous system. The substances which have a lytic effect particularly on the medullary sheaths of the central nervous system ought to be lipases. To be sure, these would not be demonstrable *in vivo*, but if lipase is present in the central nervous system, cholesterol esterases capable of intercepting and binding these lipases might be formed. In this case there would be an increased cholesterol content in the serum of patients with multiple sclerosis. The total and the free cholesterol were determined for twelve patients with multiple sclerosis, three patients with amyotrophic lateral sclerosis, one patient with neural myatrophy and two patients with chronic poliomyelitis. Then cholesterol tolerance tests were made. For the patients with multiple sclerosis, the cholesterol values were extremely high. However, the ratio of free to esterified cholesterol was normal. The suggestion that the increase in cholesterol may be due to the decomposition of the medullary sheaths is refuted by the observation that in cases of the other disorders (amyotrophic lateral sclerosis, chronic poliomyelitis and so on) the cholesterol values were normal. It is further pointed out that since the cholesterol metabolism is closely related to the adrenal cortex and the adrenals take part in vitamin metabolism, it is possible that multiple sclerosis belongs to the group of vitamin deficiencies. On the basis of this theory, the patients with multiple sclerosis were treated with vitamin C. It was found that after four weeks of this treatment the cholesterol content had become reduced. The author admits that the short period of observation permits no definite conclusions, and she still leans toward the hypothesis that the increase in cholesterol is the manifestation of a defense reaction against lipolytic ferments. However, this theory requires further proof.

Action of Carbonic Acid Baths—Ehrenpreis says that the hydrostatic pressure of carbonic acid baths exercises the same influence as that of ordinary baths and that the action of the baths depends on the temperature of the water. The baths not only regulate but also sustain the uniformity of temperature of the body. But there is a difference in the case of carbonic acid baths, which have a distinct influence on the organism of the patient through the specific action of carbonic acid. Many times he has observed objective and subjective improvement in patients with heart disease who went to a gaseous mineral water health resort for five or six weeks just to change their environment. A remarkable fact is that during their stay at the resort, usually by the end of the second week, the patients became worse and were generally weaker but noted great improvement during the third week. This temporary general debility at the end of the second week is called by German physicians "brunnenrausch." This debility is caused by gaseous air inhalations to which the patient's organism is not adapted. This observation proves that we are still in the dark as to the action of carbonic acid baths, although we know that carbonic acid acts especially on the skin by penetrating in different ways into the organism, and on the heart. The indications and contraindications of carbonic acid baths in cardiac patients should be thoroughly investigated and their dosage as to temperature, intensity, time of application and frequency should be established by further study.

 *Intraperitoneal Blood Transfusion H P J Koenen and J M M Vonk —p 320
 *Alcohol and Nicotine Poisoning in Nurslings C J Wyckherld Bisdorn —p 332

Intraperitoneal Blood Transfusion—Following a review of the literature in which they point out that intraperitoneal blood transfusion is used especially in America, Koenen and Vonk describe their own experiences with this method in forty-seven children. A tabular report lists the different conditions in which the method was employed and the results. The most favorable results were obtained in atrophies and in senous gastro-enteritides. In discussing the technic, the authors say that a donor of the same blood group should be selected. They regard as the best site for the injection the point between the lateral and middle third of the Monro-Richter line, that is, the line from the umbilicus to the left anterior superior iliac spine. The injection is made at an angle of 45 degrees, the needle pointing in the direction of the symphysis. The second transfusion, which should not be made before eight days has elapsed, is made below the umbilicus, in the median line. The authors cite other points mentioned in the literature as suitable for the intraperitoneal blood transfusion. They recommend this method of transfusion in the treatment of young children.

Alcohol and Nicotine Poisoning in Nurslings—Wyckherld Bisdorn describes the symptoms of alcohol poisoning in a breast-fed infant of 8 days, whose mother had consumed a whole bottle (750 Gm) of port. When examined, the child was in deep sleep, from which it could not be awakened, and it refused to nurse. It did not react to pain irritation, the tendon reflexes were somewhat increased, the abdominal and cremasteric reflexes were weakly positive, the pupils reacted only slightly to light. The child perspired profusely, the breathing was deep, slow and snoring, the pulse was weak and frequent. At first it was suspected that a narcotic was the cause of the intoxication, but finally the mother admitted the drinking of the port. To verify the diagnosis, blood tests were made and alcohol was detected in the blood of mother and child. The treatment of the nursing was symptomatic, recovery followed. The second case is one of nicotine poisoning in a breast-fed infant of 6 weeks, whose mother smoked twenty cigarettes a day. The symptoms were restlessness, insomnia, spastic vomiting, diarrhea, rapid pulse and circulatory disturbances. Examination of the mother's milk revealed nicotine. When mother's milk was discontinued, symptoms of abstinence appeared. Treatment was symptomatic and the child recovered.

 Experiences with Benzadrine Preliminary Report P H Reiter —p 459
 Iceland from Balneologic Point of View K Tackmann —p 461

Roentgen Treatment of Exophthalmic Goiter—Raagaard says that in sixty-eight certain cases of exophthalmic goiter (thirty-six mild cases, twenty-six moderately grave, six grave) in which mostly ambulant roentgen treatment was given from 1922 to 1933 and which were observed for from three to eleven and a half years after treatment ended, after-examination shows recovery in 70.6 per cent, almost complete recovery in 7.4 per cent, improvement in 10.3 per cent and no change in 7.4 per cent, one patient died from the exophthalmic goiter, two from other causes. There was recovery in 62.5 per cent of the thirty-two grave and moderately grave cases, almost full recovery in 9.4 per cent, improvement in 6.2 per cent and no change in 15.6 per cent, the death from exophthalmic goiter was in this group. Of the total sixty-eight patients, 85.3 per cent were fully capable of work and 5.3 partly capable. There was recurrence in six cases, or 8.8 per cent. The goiter completely disappeared in 6.4 per cent of the cases and completely or partly disappeared in 7.8 per cent. The length of time before recovery was usually from one to two years. The average duration of treatment was eleven and nine-tenths months, an average of seven and three-tenths treatments was given. No patient was rejected as unfit for roentgen treatment.

FACTORS INFLUENCING MORBIDITY IN THYROID SURGERY

CHAIRMAN'S ADDRESS

R S DINSMORE, M D

CLEVELAND

In considering the morbidity associated with thyroid surgery, one is impressed by the fact that a great deal more emphasis has been placed on preoperative and postoperative care and the mortality rates than on morbidity. The mortality rate is now almost the same in all thyroid clinics. The highest aim of thyroid surgery should be to return these patients to their normal lives as normal persons without residual symptoms. Obviously, certain pathologic conditions may have become permanent but, fortunately, these are in the minority. There is no operation that may change the physical and mental condition more strikingly than a thyroidectomy in a patient with hyperthyroidism. It is important that the factors of morbidity should be recognized prior to, during and after the operation not only to facilitate the actual handling of the patient but to aid in giving a definite prognosis. The complications in thyroid surgery may be numerous, they may not result in a fatality, but they may result in a morbid state. Fortunately, practically all the emergencies and complications of thyroid surgery can be prevented. It is within the scope of this paper to discuss only the more common factors of morbidity.

EXOPHTHALMOS

Perhaps the most frequent question asked the surgeon by the patient with exophthalmic goiter is "What will happen to my eyes?" As a general rule, if the patient is operated on early in the course of the disease, the eyes return to normal. It should be remembered, however, that many patients have a widening of the palpebral fissures and may have normal measurements with Hertle's exophthalmometer. This, of course, comes on earlier than the exophthalmos and promptly disappears after the thyroid has been removed. If the exophthalmos is of long duration and has reached a fixed position, the prognosis is quite different, as many of these patients will still have prominence of the eyes. Fortunately they gain weight, the face becomes fuller, and the exophthalmos becomes less noticeable, although the measurements may remain the same as prior to the operation. The appearance of many patients has been markedly improved by a Wheeler tarsorrhaphy.

One of the worst catastrophes that patients with exophthalmos may have is an actual protrusion of the

eye with its loss. In some cases it may be necessary to close the eyelids over the eyes to keep them in their sockets during an acute hyperthyroidism. In the severe cases in which there is a wide corneal exposure, the eyes must always be covered with a hypersaturated petrolatum gauze pad. If the exophthalmos is rapidly progressing with an accompanying severe reaction of the conjunctiva and the cornea, an emergency thyroidectomy is justified. This, of course, is a rare incident. In one instance I performed a thyroidectomy on a patient who was not properly prepared for the operation solely to save the eyes. The anteroposterior measurements were 33 mm in each eye, and the fissures had a measurement of 18 mm.

The cause of exophthalmos is still unknown and the degree of exophthalmos is not in any way an indication of the severity of the disease. After the operation, the edema of the orbit rapidly disappears because levator spasm is relieved.

One of the most distressing types of exophthalmos is the type that occurs in a small group of patients who had slight or no exophthalmos before the operation, but, with the appearance of transient hypothyroidism, the eyes became prominent. If these patients are seen early, the progress may be checked immediately by the use of thyroid extract in liberal doses. The basal metabolic rate should be determined frequently and under no circumstances should these patients again be subjected to thyroid surgery or should it be assumed without good evidence that the disease is recurring. Occasionally the progressive exophthalmos is interpreted as a recurrent hyperthyroidism. A Naffziger operation may be necessary to allow for the venous engorgement and the edema that occur about the eye. However, if the exophthalmos reaches a stationary point and frequent measurements show this to be true, the operation should be deferred. Occasional cases are seen in which the exophthalmos is unequal. So-called unilateral cases are extremely rare and in almost every instance there is a difference in the degree of exophthalmos in the two eyes rather than a purely unilateral condition. It should not be forgotten that exophthalmos may occur in several other diseases, occasionally hypertension, retrobulbar arteriovenous aneurysm and tumors, and cases have been reported in which the eyes were affected in osteitis deformans, acromegaly and leontiasis ossea.

CARDIAC MANIFESTATIONS

The morbidity associated with the heart in hyperthyroidism is dependent on (1) the age of the patient, (2) the presence of organic heart disease, (3) the duration of the disease or (4) an associated hypertension and arteriosclerosis.

Postoperatively, a moderate tachycardia in any patient is usually without significance. The most fre-

Eighty Eighth Annual Session of the American Medical Association
Atlantic City, N. J. June 9 1937.

quent and therefore the most important arrhythmia is auricular fibrillation. These patients should be watched carefully and treated. It has been our policy, if the rhythm has not been restored to normal at the end of ten days after operation, to discontinue the digitalis and give a course of quinidine. The contraindications to its use are (1) a marked enlargement of the heart, (2) a history of long standing fibrillation, that is, for one or two years, with accompanying mitral stenosis, or (3) hypersensitiveness of the patient to quinidine. The drug is not given preoperatively. If the patients with paroxysmal fibrillation as well as continuous fibrillation are included, approximately 85 per cent leave the hospital with a normal rhythm.

In elderly patients the early treatment and recognition of the condition are important, because I have seen a long series of postoperative complications in which the auricular fibrillation marked the onset. Develop in patients who had no other symptom except the auricular fibrillation. Fortunately, myocardial failure does not develop in most of these cases, but edema of the lungs may sometimes occur, which may be superimposed on a chronic bronchitis, the patches of bronchopneumonia develop and a definite mortality rate invariably follows in a given number of these cases.

The preoperative use of digitalis is a valuable adjunct in the handling of patients with hyperthyroidism if there is the slightest evidence of congestive heart failure or auricular fibrillation. No bad effects have resulted and I feel that the incidence of postoperative auricular fibrillation can be lowered by its use. Chronic auricular fibrillation will continue in many cases even though digitalis is used in large doses and it may be necessary to operate while the fibrillation is still present. In these cases, however, the pulse curve after rest in bed gradually goes down and the deficit is much lessened.

MENTAL MANIFESTATIONS

The major mental manifestations of hyperthyroidism fall into three groups: (1) the psychosis of hyperthyroidism, (2) the toxic delirium of the acute crises and (3) the delirium and mental confusion that are occasionally seen postoperatively.

The surgeon doing thyroid work is occasionally confronted with a patient who has a true major psychosis and hyperthyroidism. While it is true that isolated reports have appeared in the literature in which patients who have had a manic depressive attack, schizophrenia or psychasthenia have been cured by a thyroidectomy, these are exceptional cases and I feel that in nearly every instance the patients have their psychosis and hyperthyroidism, and the psychosis has not resulted from the hyperthyroidism. The surgeon is often called on to see these patients in institutions and he should give an extremely guarded prognosis, stating that the physical condition of the patient will be markedly improved by thyroidectomy but that no promise for improvement in the mental symptoms can be given.

Occasionally an unexpected major psychosis will develop after a thyroidectomy. Again this is a very rare complication, but when it occurs it may be serious. It should be emphasized, however, that this complication probably occurs no more frequently after thyroidectomy than after any other major surgical procedure and that a psychiatrist will elicit a history of personality changes and previous episodes of the same character. In discussing this problem with the patient's family it is important at the onset to caution them about the possibilities in such a case and to give a

psychiatric prognosis rather than one based on the fact that it is merely a postoperative thyroid state. Karnosh¹ has made a very pertinent statement regarding this group of patients, emphasizing that "frequently hyperthyroidism is merely another episode in the unstable life of many a neurotic constitution and is simply additional evidence of basic psychobiologic inadequacy and personality maladjustment. In scrutinizing the records of such cases, cause and effect often seem to be hopelessly intermingled."

The second type of mental manifestation is the toxic delirium of acute hyperthyroidism. Before compound solution of iodine was used, this was a frequent occurrence in patients with hyperthyroidism, but it is now rather uncommon, although such patients are still seen occasionally. Usually they are brought to the hospital in an ambulance. Delirium sometimes accompanies the height of the reaction in patients who have a marked tachycardia, high temperature, nausea and vomiting, diarrhea, marked restlessness and mental agitation. If the delirium lasts more than forty-eight hours, the prognosis in many instances is bad in spite of the use of compound solution of iodine, dextrose, saline solution intravenously, and blood transfusion. The intracellular change has apparently gone beyond the stage of therapeutic repair or reversal. Fortunately, the majority of these patients can be controlled with iodine therapy alone, especially if iodine has never been taken or has not been used recently. Owing to the fact that these patients have nausea and vomiting and diarrhea, iodine cannot be given by mouth or by rectum. It can be given intravenously, however, but it should not be forgotten that it is easily and quickly absorbed when painted on the skin.

The third group of patients are those in whom the postoperative delirium and mental confusion follow thyroidectomy. In my own experience, liver failure has been the most common cause. This delirium usually occurs on the second or third day and it is always noted that the icteric index is rising. It is most apt to occur in persons beyond middle life. Jaundice may be an accompanying symptom and the blood urea remains low. It is significant also that in this group of cases the blood amino acids are normal. These patients recover promptly following the use of dextrose intravenously, which replaces the diminished glycogen reserve of the liver. High carbohydrate, high caloric feedings given through a nasal tube may be effective in treating this type of delirium.

Drugs, especially in elderly persons, may be the cause of the postoperative confusion of delirium. Barbiturate rates and the prolonged use of bromides may produce these symptoms.

Another cause of postoperative delirium may be low renal function and rapid rise of the blood urea to a uremic level. A true thyroid crisis after the operation is extremely rare. The delirium in these instances must be treated with large quantities of saline solution, dextrose solution, blood transfusions, and the continued use of iodine.

Disorientation following thyroidectomy may be caused by acute hypothyroidism. This is an infrequent and transient condition, which may manifest itself on the second or third day following thyroidectomy. It is characterized by drowsiness and a peculiar glistening of the skin and nervousness, and occasionally these patients complain of numbness and tingling of the

¹ Karnosh, L. J. and Williams, G. H. Jr. Psychoses of Hyperthyroidism and Hypothyroidism. *West J. Surg.* 42: 509-529 (Sept.) 1934.

extremities without evidence of tetany. Usually nervousness and the mental confusion are mild, but disorientation may develop. Strikingly enough, these patients improve quickly with one large dose, from 6 to 10 grains (0.4 to 0.65 Gm.), of thyroid. This, of course, should be followed by small doses of thyroid daily for a few days.

IODINE

It is now almost fourteen years since iodine was first used in a routine manner in the preparation for operation of patients with hyperthyroidism. Surgeons are so familiar with its use that only a few remarks will be made about it. In spite of repeated cautions and advice, however, the surgeon still sees many patients with hyperthyroidism who have had iodine over long periods and in whom he has missed the opportunity of operating at the time of the maximum clinical improvement. They are often troublesome patients to prepare for operation. I have had the least trouble when these patients have been sent to the hospital and carried on the same dosage of iodine which they had been taking. Whenever an attempt has been made to discontinue or change this, difficulty has ensued. They derive some benefit from mild sedatives and complete rest in bed for a few days. Oftentimes the pulse rate will drop 18 or 20 points with this alone. If there is evidence of congestive heart failure, a course of digitalis also is begun.

The surgeon must always answer the question as to whether or not patients should have iodine after leaving the hospital. Probably each patient should be individualized and, if the gland was found at operation to be extremely friable and hyperplastic, small doses of iodine should be taken for thirty days after the patient has left the hospital. In most cases it is unnecessary as these patients have had the maximum amount of improvement which they will receive from iodine.

The other indication for iodine from the surgical standpoint is in mild recurrent hyperthyroidism. Haines and his co-workers² have emphasized the importance of using small doses of iodine in these cases. The question arises as to whether or not the symptoms caused by many of the so-called recurrent goiters are not the result of a residual hyperthyroidism. Occasionally a patient is seen who gains weight after the operation, feels quite different, and has a complete loss of tremor and nervousness although he still has a persistent afebrile tachycardia. In such cases the addition of small doses of iodine for two or three months will often obviate the necessity of a second operation.

Although the clinical use of iodine is probably a medical problem, the surgeon who is handling patients with thyroid disease is repeatedly called on to state whether or not iodine should be used in a given case. It should be borne in mind that the clear-cut indications for the use of iodine are

1 Small doses during pregnancy, especially to women who have enlargement of the thyroid.

2 As a prophylactic measure in doses of 10 mg. a week for school children.

3 To the adolescent boys and girls who have simple goiters.

4 As a preoperative medication in all patients with hyperthyroidism, regardless of the type of gland.

5 In cases of residual or recurrent hyperthyroidism.

6 As a therapeutic test in borderline cases.

In my own experience it is of questionable value in cases of acute thyroiditis. In a few instances some relief from pain has followed its administration.

2 Haines, S. F. The Use of Iodine in Recurrent Exophthalmic Goiter, *Tr. Am. As. for the Study of Goiter* 185-191, 1934.

In this regard, the question of the value of blood iodine studies arises. Although the procedure may have distinct diagnostic value, its application is limited. Certainly there is no indication for its use in the presence of frank hyperthyroidism. It may, however, be of some value in making a differential diagnosis when it is difficult to determine the basal metabolic rate, such as in hypertension with a high basal metabolic rate, certain psychoses, hyperthyroidism in young children, and encephalitis. In spite of the simplification of the technic, it is still a rather difficult laboratory procedure. In many of the borderline cases it has been pointed out that the chief value comes in finding a normal blood iodine. Also, there are patients who have clear-cut hyperthyroidism with normal blood iodine. Lahey³ has reported similar observations.

TECHNIC OF THYROIDECTOMY

While it is impossible to discuss technical details, it must be borne in mind that many satisfactory techniques for thyroid surgery have been described. After all, a satisfactory technic is the one that can be carried out in a reasonable length of time under some form of light anesthesia or analgesia, augmented by local anesthesia, which protects and preserves the recurrent laryngeal nerves and the parathyroid bodies, one in which a proper amount of thyroid tissue is removed, one that gives a good cosmetic result, and, above all, one that cures the patient. It must not be forgotten, however, that a definite morbidity rate may be directly attributable to the operation. In my own hands, the protection of the recurrent laryngeal nerves is best carried out by first dissecting the lateral borders of the thyroid gland and placing three pilot clamps, one on the superior thyroid vessels, one on the inferior pole, and one on the lateral thyroid vein. The clamp at the superior pole is always applied from within outward, care being taken to have the pole of the gland separated from the laryngeal box. The clamp at the inferior pole is placed in such a position that a small amount of thyroid tissue is caught with the clamp to insure a high ligation of the inferior thyroid artery, and so that the clamp will stand erect in the wound after it has been applied. The third clamp is placed on the lateral thyroid vein. After these three points are divided, the gland can be dislocated forward and dissection carried from the midline. Such a method allows one to place the clamps in a horizontal direction rather than directly toward the tracheo-esophageal groove, the result being a pyramidal piece of thyroid tissue which completely covers this groove. An important technical point for the protection of the parathyroid bodies is to leave intact all the capsule of the thyroid. This, along with high ligation of the inferior thyroid artery, will result in a very low incidence of parathyroid injury.

Still the most difficult technical problem in thyroid surgery is to know exactly how much thyroid tissue to remove and have a perfectly normal individual afterward. Often patients are seen at the end of a year stating that they feel perfectly well and that their subjective symptoms have all disappeared. However, on closer questioning, it is found that they tire easily, often have to sleep long hours and even after doing so are still tired, and have a dryness of the skin and a tendency to gain weight. Thyroid surgery should not

3 Perlman, H. J., Lahey, F. H., and Cattell, R. B. Blood Iodine Studies in Relation to Thyroid Disease. Basic Concept of Relation of Iodine to Thyroid Gland. Iodine Tolerance Test. *New England J. Med.* 214: 45-52 (Jan. 9) 1936.

only aim ultimately for the relief of the subjective symptoms but should leave no objective or physical signs of either hypothyroidism or residual hyperthyroidism. It should not convert one pathologic state into another.

One of the technical problems in thyroid surgery that should be emphasized is the difficulty of removing a thyroid in recurrent hyperthyroidism. Again it is important that the dissection should first be on the lateral borders of the gland. Often the carotid sheath is adherent to these markedly hyperplastic adherent glands. If it is first dissected free, many of the technical difficulties may be obviated. Fortunately, many of these glands have a rather dense capsule and by sharp knife dissection these lobes can be dislocated forward and the same principle of the protection of the tracheo-esophageal groove carried out as described previously. Many of the primary landmarks are lost and it is extremely important that this area be protected for its entire length.

POSTOPERATIVE COMPLICATIONS

Certain complications that may arise after a thyroidectomy may be the direct cause of morbidity. Even with meticulous care and careful hemostasis, hemorrhage may follow the operation. If the hematoma forms rapidly, it may cause symptoms of suffocation and the pressure must be relieved at once. However, these hematomas should be evacuated carefully and if possible with a full operating team. Such a hemorrhage may mark the onset of a long series of complications such as nerve injury, tracheitis and infection. In the haste to evacuate the clot, several vessels may be torn, whereas in nearly every instance the bleeding is from only one vessel. An extravasation of blood has destroyed the normal landmarks and the recurrent laryngeal nerves may easily be injured during the procedure. The simplest method of handling these cases is to place the fingers beneath the posterior aspect of the gland, dislocate it forward, and after gently sponging and releasing the pressure, the bleeding point usually can be seen clearly. If one is unfortunate enough to have a ligature slip off the superior thyroid artery, it may retract well up into the neck. In such instances it is almost impossible to see the bleeding point. Pressing the carotid artery against the vertebral column, carefully sponging until the wound is practically dry and then slowly releasing the pressure will enable one to see the point of hemorrhage.

There is another type of hemorrhage that may occur either at the operation or postoperatively and may be difficult to recognize early. This type of hemorrhage practically always occurs in an intrathoracic goiter. This is the so-called mediastinal extravasation. Usually there is no bulging in the neck and no increased bleeding from the rubber tissue drain, which is always inserted for twenty-four hours. Clinically these patients become very pale, a weak thready pulse develops, there is a slight increase in mediastinal dullness, and there are slightly distant heart sounds. This extravasation may occur either in the posterior or the anterior mediastinum and cause severe cardiac embarrassment and compression of the great vessels in the superior mediastinum. The prognosis in these cases is universally bad. Fortunately in nearly all cases of intrathoracic goiter the cavity from which the thyroid is removed is quickly obliterated by the lungs and pleura. However, there is a type of long standing intrathoracic goiter in which the cavity is a partially fixed one and

is not obliterated by the time hemostasis is completed. It is this type of case in which such an extravasation may occur. For this reason a secondary closure is often done.

The appearance of stridor after a thyroidectomy is always a disconcerting symptom and may indicate that a recurrent laryngeal nerve has been injured or that there is edema of the larynx or glottis. The latter two conditions usually cause a slowly developing stridor. If any stridor does not disappear quickly or if the patient shows any cyanosis, tracheotomy should be performed without delay. Often these patients will very quickly become extremely restless, a stage of exhaustion is reached, and the internal respiration becomes so damaged that tracheotomy may be done too late. These patients always have a peculiar type of nervousness and restlessness and it is striking to see them sleep for long hours after a tracheotomy. It is important to do the tracheotomy with a transverse incision between the tracheal rings and remove the tube as soon as possible, often in from twelve to eighteen hours. A true collapse of the trachea is extremely rare and the so-called saber sheath trachea occasionally seen during operation is most likely due to a spasm of the vocal cords, as postoperative laryngoscopic examination will usually show a paresis of one cord. During an operation, however, I have seen stridor develop which was quickly followed by cyanosis and the formation of a so-called saber sheath trachea. As soon as an opening is made into the trachea it quickly resumes its normal shape, and often it is possible to close the trachea at the completion of the operation. Laryngeal examination will show that both cords may be functioning normally.

Oxygen therapy has been a distinct adjunct in the postoperative management of elderly, severely ill and bad risk patients with hyperthyroidism. These patients are placed in the tent immediately after the operation and are kept there for from twenty-four to forty-eight hours. The temperature can be lowered, respirations are easier, cyanosis, if present, clears up quickly, and the amount of postoperative mucus apparently is diminished. Although there is no absolute evidence to show that the incidence of postoperative pneumonia is less, I feel that there is a definite decrease in the mortality rate in any type of postoperative pneumonia with the use of an oxygen tent. It is always impressive to have these patients ask that the tent be kept in place, stating that it is easier for them to breathe and sleep and that they are more comfortable in the tent than after it is removed.

The management of the patient with a pulmonary complication needs no comment except to state that in spite of all effort at prevention there is a small group, usually elderly persons, in whom considerable mucus develops in the trachea and bronchi. These patients apparently do not have sufficient strength to cough up the mucus, and therefore more and more accumulates in the tracheobronchial tree. In spite of an oxygen tent, shock position and all supporting measures, the temperature rises, cyanosis develops, generalized rales are heard and bronchopneumonia appears imminent. Following a tracheotomy an enormous amount of mucopurulent material may be aspirated from the trachea and bronchi, and dramatic improvement may follow such a procedure.

The development of acute tetany postoperatively is a terrifying experience to the patient and often almost as disconcerting to the surgeon. However, it should

be borne in mind that the severity of the attack may not in any way indicate that chronic tetany will develop. Treatment depends entirely on the administration of calcium in a quickly available form. The most effective of all the calcium compounds is calcium chloride, of which 10 cc of a 10 per cent solution is given, care being used lest a slough develop. For this reason, if the attack is not severe, the calcium can be given slowly in saline solution. My experience has been that no other calcium compound gives the prompt relief that the calcium chloride does. It should be pointed out that parathyroid extract is not necessary in these cases. At the time the calcium is given it is usually advantageous to give morphine, and the intravenous administration of dextrose solution will have a beneficial effect. Ordinarily a teaspoonful of calcium lactate powder given three times a day after this is sufficient for the care of these patients in the hospital, the dose being about 175 grains (11 Gm) a day. The use of phosphates in any form is to be strictly avoided, as it is distinctly harmful in the presence of tetany. Catharsis is contraindicated. It has been noted that the attacks of tetany may appear when the serum calcium is at the same level as when the patient is free from symptoms. Under such circumstances the attacks are usually caused by an increase in the blood phosphates, and the indication in these cases is the administration of lactose, which reduces the blood phosphate content. From three to six teaspoonfuls a day is usually sufficient. Frequent estimations of the blood calcium and phosphorus must be made for the intelligent treatment in these cases. Fortunately the complication is a rare one, and even though the initial attacks in the hospital may be severe they are possibly caused by the edema or temporary cessation of the function of the parathyroid as a result of the operative procedure, and a pessimistic prognosis need not be made.

RECURRENT HYPERTHYROIDISM

The incidence of recurrent hyperthyroidism is usually somewhere between 2 and 3 per cent and within recent years I have been impressed by the fact that the incidence of hypothyroidism is far greater than the incidence of residual or recurrent hyperthyroidism. For that reason, in attempting to secure a result in which neither of these clinical syndromes is present I have as a general rule removed a little less tissue in the purely hyperplastic glands. This is particularly true in children with exophthalmic goiters. Haines² has made an important contribution, pointing out that it is possible to control a certain percentage of recurrent cases with small doses of iodine over relatively long periods of time. The symptoms on the whole are much more mild than in the primary instance. However, if the patient returns with increasing nervousness and a persistent afebrile tachycardia for which there is no etiologic factor, a secondary operation will in all likelihood have to be performed. In many of these cases it may be difficult to palpate an enlargement, but this does not in any way preclude the indication for operation. Generally speaking, more thyroid tissue is found than one had anticipated from the physical examination of the neck. However, extreme care should be used in the exploration and, even though a large nodule is found deep in the neck on one side, the opposite side should always be thoroughly exposed, the tendency being in such an instance to feel that one nodule is the cause of the recurrence and to overlook a similar one on the opposite side. Many of these nodules have

occurred at the upper pole and for that reason in the primary operation I have preferred to leave a little thyroid tissue at the inferior pole and to dissect the upper pole perfectly clean. Scott⁴ has recently emphasized the importance of the projections, which may have occurred posteriorly, and they should be searched for carefully. Likewise, the remnants of the inferior thyroid pole should be looked at, as occasionally an intrathoracic projection may be present. Oftentimes one finds only what one considers rather small nodules that would not appear to have caused the recurrence, curiously enough, on gross section they appear completely involuted and fibrosed, yet the patient will go on to a complete clinical cure.

COMMENT

In a general way the foregoing discussion represents the more common factors contributing to the morbidity in thyroid surgery. Emphasis has been placed on some infrequent complications, but they are extremely important should they develop. It has been stated that the function of thyroid surgery is not to convert one pathologic state to another, nor is it enough to have the patient merely improved, the completed end result should always be to have the patient free from any symptoms that may be attributed to the thyroid gland.

2020 East Ninety-Third Street

THE STONELESS GALLBLADDER

AN ANALYSIS OF ONE HUNDRED CASES TREATED
BY CHOLECYSTECTOMY

CARL A. KUNATH, M.D.

IOWA CITY

During the past few years a number of articles have appeared in the literature in regard to the noncalculous gallbladder and the less satisfactory results following cholecystectomy in this type of case.¹ Since the advent of cholecystography, the diagnosis of chronic cholecystitis has become much more common and there has come about a gradual acceptance of a broader symptomatology in gallbladder disease. These newer symptoms are supposed to be associated with disturbances in the function of the gallbladder and include gaseous indigestion, inability to digest fatty or greasy foods, belching, distention, vomiting and flatulence. It is largely through the acceptance of this "dyspepsia syndrome" in gallbladder disease that the problem of the stoneless gallbladder has arisen.

The present study is based on a follow up of 100 consecutive cases of cholecystectomy carried out on stoneless gallbladders in this clinic during the eight year period between March 1, 1927, and March 1, 1935. These are all uncomplicated cases in which no operative procedures other than cholecystectomy were carried out on the biliary tract. All cases of acute cholecystitis were discarded. Cases in which only a cholecystostomy had been done and cases in which the common duct had been opened were discarded. The follow-up study was carried out chiefly by a questionnaire letter, although a fair number of the patients were available for study in the outpatient clinic.

⁴ Scott A. C. Jr. The Surgery of Recurrent Exophthalmic Goiter. *Texas State J. Med.* 32: 649-652 (Feb.) 1937.

From the Surgical Service of the University Hospitals, State University of Iowa College of Medicine.

¹ Dwyer M. F. and Dowling G. A. Results in Cholecystectomy with Special Reference to the Symptomatology and Diagnosis of Cholecystitis. *J. A. M. A.* 95: 722-725 (Feb. 27) 1932. Mackey², Graham and Mackey³, Palmer⁴, Judd⁵, Andrews⁶, Weir and Snell⁷.

For purposes of comparison, a similar follow-up study was made of 100 consecutive cases of chronic cholecystitis with cholelithiasis that came to operation. The cases in this group also represent those in which only a simple cholecystectomy was done. The statistical data of these two groups are shown in table 1.

The age incidence in the two groups was almost identical, it averaged 42.3 years in the noncalculous group and 41.9 years in the calculous group. The theory that the noncalculous cases represent the earlier cases in respect to duration of symptoms was not borne out, the average duration of symptoms before admission to the hospital being practically the same in the two groups.

Females outnumbered males in each group but there were more males in the noncalculous group than in the group with stones. This may or may not be of significance.

When one turns to the symptomatology, it is naturally found that the symptoms are more pronounced in the group with calculi. Of interest, however, is the fact that 56 per cent of the noncalculous cases gave a history of biliary colic. These patients all had a very severe colicky type of pain in the epigastrium or beneath the right costal margin, radiating to the right side of the back or scapula and requiring hypodermics for relief. It would appear, therefore, that one must look for other causes than calculi in the production of the type of pain usually referred to as biliary colic. This has also been observed in the series of cases reported by Mackey,² Palmer,³ Muller⁴ and Smithies.⁵ It is also of interest to note that the percentage of patients who gave a history of jaundice was the same in the two groups of cases.

Cholecystography was carried out in fifty-five cases in each group, which makes the figures convenient for comparison. Although the visualization of stones must be considered a more or less incidental finding in the cholecystograms, it was possible to make a diagnosis of cholelithiasis in 40 per cent of the calculous cases in which the test was made.

In regard to the microscopic aspect of the removed gallbladder, it is noted that nearly one fourth of the cases in the noncalculous group were reported as normal. The foregoing pathologic classification was used in order to conform as closely as possible to that used in other series of cases in the literature.⁶

In respect to the postoperative courses of the two groups, one sees that 17 per cent of the noncalculous group had stormy courses as compared with only 7 per cent of the group with stones. Wound infections were more frequent, and of the eight severe wound infections in the noncalculous group there were four complicated by evisceration.

There were six postoperative deaths in the stoneless group—a postoperative mortality of 6 per cent as compared with 1 per cent in the calculous group. One gained the definite impression in reading over the records that the morbidity as well as the mortality was much higher in the stoneless cases. There was a greater tendency to postoperative distention, nausea and vomiting, and more sedation was necessary.

An estimation of the end results was obtained in 83 per cent of the noncalculous and in 83 per cent of the calculous cases. According to the patient's own statement, only 26.1 per cent of the patients without stones could be classified as "cured." Cures or improvement were obtained in 69.6 per cent of this group as compared to 84.3 per cent in the cases presenting cholelithiasis. Such results are in keeping with those reported from other clinics.⁷

The question naturally arises as to whether there are any factors which might help one to anticipate these poor results and in this way enable one to prognosticate as to the relative benefits of cholecystectomy in a given case.

TABLE 1—Comparison of Follow-Up Study on Calculous and Noncalculous Series

Data	Noncalculous	Calculous
Number of cases reviewed	100	100
Average age	42.3 years	41.9 years
Sex		
Male	24	14
Female	76	86
Average duration of symptoms before admission	6.37 years	6.5 years
Symptoms		
Typical biliary colic	56%	84%
Dyspepsia syndrome	70%	75%
Vomiting	71%	80%
Jaundice	38%	38%
Cholecystographic evidence	55%	30%
Gallbladder not visualized	18 (32.7%)	33 (60%)
Gallbladder only faintly visualized	12 (21.9%)	9 (16.4%)
Good visualization	9 (16.4%)	9 (16.4%)
Impaired function	3 (5.5%)	1 (1.8%)
Gallbladder shadow distorted	3 (5.5%)	3 (5.5%)
Normally functioning gallbladder	13 (23.6%)	3 (5.5%)

Pathologic Changes—In regard to the pathologic changes in the gallbladder, I find that, in a general way, the percentage of good results rises steadily as the pathologic processes in the gallbladder becomes more advanced (table 2).

The chief exception to this rule is the group presenting cholesterosis, or so-called strawberry gallbladders, in which the percentage of cures is even lower than in the group presenting normal gallbladders. Mackey and Stanton⁸ both feel that the "strawberry gallbladder" is neither pathologic nor symptom producing. On the other hand, Lahey⁹ believes that it is productive of symptoms which are relieved by cholecystectomy. Our group is small (nine cases), but the results would seem to favor the former view.

Perhaps the most significant figure in table 2 is the relatively high percentage of cures in the group of patients with normal or nearly normal gallbladders. It is this figure which discourages the surgeon from placing too much prognostic value on the pathologic report. Pathologists must admit, as Maynard¹⁰ has, that many patients do get relief from their symptoms after removal of gallbladders showing very little pathologic change. Although the pathologist can help in respect to anatomic deviations from the normal, he has no way of estimating what constitutes a normal gallbladder from a physiologic or functional point of view. It appears that in many of these cases one is dealing with a condition of abnormal mechanism or disturbed function without anatomic change. For this reason the histologic changes in the gallbladder wall are not always an accurate index of the symptoms that the organ has produced or of the benefit that may result from cholecystectomy.

Cholecystography—During recent years both the surgeon and the internist have been placing an increasing amount of reliance in cholecystography as a means of diagnosing gallbladder disease. In this clinic we have felt that the test is accurate in well over 90 per cent of the cases and only very rarely do we advise cholecystectomy in the face of a normal cholecystogram. Table 3 shows the end results in our series of cases in respect to the cholecystographic evidence that was available.

Of significance is the fact that, of the cases in which there were normal cholecystograms, there were cures or improvement in 75 per cent. These figures are difficult to explain. Graham and Mackey¹¹ encountered the same discrepancy in their series, the percentage of cures or improvement being the same in the group of patients with normal cholecystograms and in the group with nonvisualizing gallbladders (60 per cent). No attempt is made to explain this matter other than to mention that perhaps incidental appendectomy is responsible for the cures obtained in the group with normal cholecystograms.

The problem becomes even more confusing when the cholecystographic evidence is compared with the changes in the gallbladder revealed by microscopic examination (table 4).

Of the fifty-one cases in which the gallbladder was not visualized there were three normal and fourteen nearly normal gallbladders. One is obliged to conclude, along with Mackey² and Palmer,³ that the cholecystogram is simply another contributing factor in the diagnosis of gallbladder disease and that it cannot be relied on entirely either in diagnosis or in estimating prognosis after cholecystectomy. During the past few years there have appeared in the literature articles dealing with faults in the present cholecystographic technic. In this clinic it has been learned that the existence of diabetes mellitus may occasionally bring about false positive reactions if the usual technic is used. We have also come to realize that duodenal ulcer or spastic conditions of the gastro-intestinal tract may cause false positive reactions.

Clinical Symptoms—Burden,¹² Sanders,¹³ Judd,⁶ Palmer,³ Graham and Mackey¹¹ and Mackey² have all

expressed the opinion that, in estimating the probable benefits to be derived from cholecystectomy, the symptoms are much more reliable than either the cholecystographic evidence or the pathologic report. The feeling seems to be that definite biliary colic is the indication *par excellence* for cholecystectomy as well as the symptom most likely to be relieved by this procedure. Many hold the opinion that if colic has occurred a satisfactory outcome from cholecystectomy may be practically guaranteed. It is the vague dyspeptic symptoms that tend to persist after cholecystectomy, and the patient operated on for these symptoms alone is quite likely to obtain no relief from the procedure.

TABLE 2—End Results of Cholecystectomy in Respect to Pathologic Changes Present in the Gallbladder

Pathologic Report	Cured per Cent	Improved per Cent	Unimproved per Cent	Postoperative Deaths per Cent

Moderate	52.6	26.3	21.1	
Marked	59.4	31.2	6.2	3.2

Table 5 shows the highest percentage of cures in the patients who had colic but no dyspepsia and the lowest in those having dyspepsia but no colic. The complaints of the vast majority of patients in the "improved" group were those of dyspepsia. In other words, it is the persistence of the dyspepsia syndrome which places the majority of these cases in the "improved" rather than in the "cured" category.

Of the patients who were followed in the stoneless group, forty-three complained of colic preoperatively. There was relief following operation in 86 per cent of these cases. There were fifty-two patients with dyspepsia prior to operation, and at the time of the

TABLE 3—End Results of Cholecystectomy with Respect to Cholecystographic Evidence

Normal gallbladder	12	41.7	33.3	16.7	8.3

follow up (from one and a half to nine and a half years later) thirty-five still had dyspepsia. In other words, dyspepsia was relieved in only about 33 per cent. Furthermore, of twenty-six patients whose histories did not include the dyspepsia syndrome preoperatively, ten now claim dyspeptic symptoms (38 per cent). It is difficult to escape the conclusion that the removal of the gallbladder was directly responsible for these postoperative digestive disturbances. It is observations such as these that have given rise to the view of Stanton,⁸ Palmer,³ and Mackey² that the so-called gallbladder dyspepsia is in reality quite independent of the gallbladder and due to causes not associated with the gallbladder.

Numerous explanations have been given to account for the poor results obtained by cholecystectomy in the

noncalculous gallbladder For the most part these explanations can be classified under three main headings (1) errors in diagnosis, (2) residual pathologic changes and (3) physiologic causes

ERRORS IN DIAGNOSIS

Possibly the most common lesion to be mistaken for cholecystic disease is duodenal ulcer Two patients in this series who were unrelieved following cholecystectomy were subsequently found to have duodenal ulcers that had been missed at the time of the original laparotomy One patient had an associated duodenal

per cent, Deaver and Bortz¹⁶ in 35 per cent Muller found pancreatitis present in 5 per cent Deaver and Bortz reported it in 12 per cent Weir and Snell¹⁷ estimate that about 20 per cent of all patients with cholecystitis have associated lesions such as pancreatitis, hepatitis and cholangitis

In the present series of cases hepatitis was noted only four times (table 1) The follow up revealed one patient cured, two improved and one dead Pancreatitis was also noted four times The follow up revealed two patients cured, one improved and one unimproved

On the whole, there is no convincing proof in the literature that the continuation of symptoms after cholecystectomy is due to these minimal changes seen in the liver and pancreas so commonly at the time of operation Martin¹⁸ believes that the mild form of hepatitis regularly found with cholecystitis has little or no clinical significance In the more advanced forms of pancreatic or hepatic involvement the relationship to postoperative symptoms is probably better justified It would appear that very few of our own failures in the treatment of noncalculous cholecystitis can be explained on the basis of residual pathologic changes Granting the occurrence of an occasional case of overlooked common duct stone, stricture or angulation of the common bile duct, reformed gallbladder or chronic pancreatitis of a sufficient degree to cause symptoms, it would appear that one must still look elsewhere to find the explanation for most of the poor results

PHYSIOLOGIC CAUSES

The unsatisfactory results after cholecystectomy in the stoneless gallbladder have led to increased interest in the physiology of the biliary tract As a result, a vast amount of experimental data has accumulated in regard to gallbladder function, and the spotlight has been focused on the sphincter of Oddi as an important mechanism in the symptomatology of biliary tract disease Whereas the teaching of the past has been that the gallbladder could be sacrificed without in any way impairing normal health, there is now, in the light of recent experiments, considerable evidence against such a view Eiss and Whaley¹⁹ list a number of both

TABLE 4—Comparison of Cholecystographic Evidence with Microscopic Condition Found in the Gallbladder

Cholecystogram	Microscopic Anatomy				
	Normal	Minimal	Strawberry	Moderate	Marked
Gallbladder not visualized	3	14	1	10	14
Gallbladder faintly visualized	4	5		7	4
Gallbladder well visualized, impaired function	7	3	1	0	
Gallbladder shadow distorted	1	3	0	0	1
Normal gallbladder	3	0	3	1	0

diverticulum Another patient returned one month after operation and was found to have a tuberculous process involving the eleventh and twelfth dorsal vertebrae Stanton⁸ emphasizes cardiac disease as a frequent cause of diagnostic error Other possible sources of error are gastric lesions, pancreatic lesions, diseases of the right kidney, syphilitic cirrhosis, chronic intestinal obstruction, hypertrophic arthritis of the spine, and intercostal neuralgia I have seen several patients with gonococcal peritonitis operated on for symptoms suggesting gallbladder disease and have found the telltale "violin string" adhesions between the liver and the anterior parietal peritoneum

Perhaps the most difficult problem from a diagnostic standpoint is the one presenting a neurosis or an irritable gastro-intestinal tract Time and again, when patients in this series have returned following operation because of persisting dyspepsia, we have by barium sulfate enema discovered a markedly spastic colon Time and again we have seen these dyspepsia symptoms disappear under a medical regimen of smooth, low residue foods and antispasmodics Indeed, the association of an irritable gastro-intestinal tract with the flatulent dyspepsias of so-called chronic cholecystitis is so frequent that I have wondered about the possible coexistence of a "spastic biliary tract" to account for the symptoms Eternal vigilance is necessary in these borderline cases if diagnostic errors are to be avoided

RESIDUAL PATHOLOGIC CHANGES

Every surgeon who is experienced with surgery of the biliary tract is familiar with the mild degrees of hepatitis, pancreatitis and cholangitis which are frequently present, and many authors have attempted to explain the poor results of cholecystectomy on the basis of this residual pathologic condition There is no general agreement, however, as to just how commonly these changes are found Olch¹⁴ found hepatitis almost constantly associated with chronic cholecystitis, Black¹⁵ reports hepatitis present in 46 per cent, Muller⁴ in 7

anatomic and physiologic changes that occur in the biliary tract following cholecystectomy and state that this operation may actually inaugurate a new cycle of disturbed function by depriving the liver of a reservoir in which to store up bile Ivy and Bergh²⁰ have also postulated various physiologic disturbances to explain the symptoms following cholecystectomy Andrews²¹

advances the theory that the dyspepsia symptoms seen so often in chronic cholecystitis are in reality the symptoms resulting from a gallbladder which has lost its function as a reservoir for bile. The syndrome may be brought about by closure of the cystic duct by inflammation or stone, or it may be brought about by cholecystectomy.

Although these physiologic considerations are to some extent theoretical and are based largely on animal experimentation, they are for the most part logical and give promise of going further in truly explaining the poor results than any of the other factors considered here.

There remains the problem of explaining the good results. How can one explain the 24 per cent of patients with normal gallbladders histologically who report that they have been cured by cholecystectomy? From a purely hypothetical standpoint, one might presume that these were cases in which the symptoms were due not to gallbladder disease but to a spastic or hypertrophic sphincter of Oddi. Removal of the gallbladder in such a case might result in a dilatation of the common bile duct and an increased intraductal pressure which might conceivably overcome this spasm and bring about a relief of the symptoms.

Others might attempt to explain the results in these cases by virtue of the incidental appendectomy which is performed in a large percentage of the cases. It is, of course, difficult to evaluate the role of incidental appendectomy in the production of cures, but from the figures at hand it appears that this procedure added little, if any, to the chances of a cure. Both Mackey² and Maynard¹⁰ have analyzed their cases with this factor in mind and have come to a similar conclusion.

Finally one must consider the psychogenic factors which are present in not a few of the cases and realize that the psychotherapeutic effect of a laparotomy may explain some of the peculiar results.

SUMMARY AND CONCLUSIONS

Another analysis of surgical cases of noncalculous "cholecystitis" has been added to the literature for the statistical value it may afford. Compared with a similar series of cases in which stones were present, one finds that the stoneless cases show a greater morbidity, a higher postoperative mortality and only about half as many cures.

The stoneless cases have been analyzed carefully from the standpoint of pathologic changes present in the gallbladder wall, and from the standpoint of cholecystographic evidence but little help is offered from either of these sources in regard to prognosis following cholecystectomy. In general, the end results tend to be better as the pathologic changes become more marked, but there are many queer aspects which are difficult to reconcile.

An analysis of the preoperative symptoms is probably of greater value than anything else in estimating the probable benefits to be obtained from cholecystectomy. We were able to cure colic in 86 per cent of the cases in which it was present. In regard to dyspepsia, we were able to bring about cures in only 33 per cent. Furthermore, of the patients who did not complain of dyspepsia prior to operation, 38 per cent now report that they have such symptoms. This would seem to be a strong argument in favor of the view that the dyspepsia syndrome is related not so much to disease of the gallbladder as to nonfunction of the gallbladder.

In attempting to explain the poor results following cholecystectomy, we were able to find a few definite

errors in diagnosis. These included duodenal ulcers, a duodenal diverticulum, a tuberculous spondylitis and a chronic gonococcic peritonitis. By far the majority of diagnostic errors were associated with cases of irritable intestine and spastic conditions of the gastro-intestinal tract.

Although a few poor results could possibly be ascribed to residual pathologic changes in the pancreas, liver or bile ducts, it was not possible to incriminate definitely any of these organs.

I believe that the greater majority of the unimproved cases must be explained on a basis of physiologic changes or altered function. There is probably a large group of cases in every series of stoneless gallbladders lying on the borderline between organic and functional disease, these are the cases in which diagnosis is difficult and in which cholecystectomy is apt to be disappointing.

The hope for improvement in the treatment of the stoneless gallbladder appears to depend on a better understanding of the physiology of the biliary tract. It is entirely likely that this improvement will be in the form of more intelligent medical management based on a sound knowledge of the common morbid physiologic changes that occur in the biliary tract. In the meantime cholecystectomy should be advised in such cases only after exhaustive study has been carried out, and the patient should not be promised too much. He should be warned that he may still have difficulty after the operation in digesting large heavy meals or fatty food and that dietary measures may be necessary.

THE STUTTER-TYPE CHILD

THE SPEECH INDEX OF NEUROTIC BEHAVIOR

JAMES SONNETT GREENE, MD

Medical Director National Hospital for Speech Disorders
NEW YORK

Last year at the National Hospital for Speech Disorders 2,203 patients were registered. Of this number 695, or about one third of the total registration, were children. These patients suffered from various anomalies of speech and voice, which were classified under the headings of dysphemia, dyslalia, dysphonia, aphasia and associative dysphasia.

In dealing with these disorders, I have found that a simplified analytic base is most useful. The tendency to become theoretically involved in extensive classifications and terms has been baffling to persons studying the subject. As in other branches of medicine, so in this, with the accumulation of knowledge and insight, unwieldy descriptive classifications have given way to simple dynamic groupings.

The best way to visualize the groupings of clinical material is shown in the accompanying table. The majority of the patients came under the first three groups: dysphemia—stuttering, dyslalia—functional and organic defects of articulation, and dysphonia—functional and organic defects of the voice.

The two terms stuttering and stammering are often used interchangeably but, according to derivation, stuttering stands for labored, difficult hesitant speech with resultant defective conversation. Stammering

Read before the Brooklyn Academy of Pediatrics of the Kings County Medical Society, Brooklyn, March 24, 1937.

The term stutter type was first used by the author in a paper read before the New York Neurological Society at the New York Academy of Medicine, Dec. 4, 1934. Treatment of the Stutter Type Personality in a Medical Social Clinic.

refers to defects of articulation and should never be confused with stuttering. In other words, stammering depends on defective performance while stuttering depends on emotional disturbances.

By far the most important group is that of dysphemia—stuttering—and the major part of this paper will therefore be devoted to the stutter-type child. However, before introducing the subject it may be well to orient it in the general field of speech pathology. I will begin with a few preliminary remarks about some of the most frequent defects of articulation, or dyslalia.

Although a child's articulate speech usually begins at the age of about 9 months, there is no need for the parents to worry if it is delayed until the age of 2 years, provided the delay is not due to impaired hearing. However, absence of speech at 2 or 2½ years should be considered abnormal.

Aside from impaired hearing, the absence of speech at 2 or 2½ years may be due to functional conditions

In this connection, another important point to remember is that one sound ear is quite adequate for learning and discriminating speech sounds. Further, it is important to differentiate between a condition of conduction deafness and one of perception deafness. In the former the middle ear is impaired, while in the latter the inner ear—that is, the cochlear branch of the eighth nerve—is affected, so that the ear is mechanically sound but neurologically unsound.

A considerable group of cases falls under the category of oral inaccuracies—lalling, infantile speech, agtrophasia (cluttering), substitutions and phonetic defects. In general, the cause in this group, aside from malformations of the organs of speech, is mainly environmental. The condition of infantile speech, or baby talk, is a striking example. The most evil outcome of talking baby talk to young children, and particularly of imitating their omissions and substitutions of consonants, because it sounds "so cute," is that such mutilated speech often becomes confirmed in the child as a habit and thus remains throughout his adult years, when it sounds far from cute to any one. Scarcely anything could be better designed to confirm defective speech in a child than hearing such speech constantly imitated.

An exaggerated form of oral inaccuracies to the point of partial or complete unintelligibility is termed idio glossia. It is, in fact, a fanciful individual language which some children develop. Several years ago three siblings, whose language, although intelligible to them, could not be understood by any one else, not even by their parents, were under treatment at the hospital. In some cases, as in this one, the personal and family histories are irrelevant. In other cases, however, a family history of neuropathy is present.

Lisping is still another form of dyslalia, the term is used to designate sound substitution in many instances. It is an infantile poor speech habit which has been allowed to become fixed. While the term lisping is frequently used to cover the entire field of letter substitution, it is chiefly used as a term for the substitution of the letter s.

The term sigmatism is also used to designate difficulties with the s sound, and many subdivisions have been made under this heading, such as interdentalis, lateralis, addentalis and nasalis, depending on various anomalies of the mouth.

Rhinolalia, nasal inarticulate speech, is speech of a nasal character due to disturbances in the vocal vibrations which pass from the oral to the nasal cavity, producing nasal out of non-nasal sounds. During normal breathing the soft palate hangs loosely, so that there is a communication between the nasal cavity and the oral cavity. When the mouth is closed, the soft palate, which is held somewhat tense, is swayed by the respiratory currents in a passive manner.

For all sounds except the nasals, m, n and ng, the velum, or soft palate, moves upward, almost entirely closing off the oral cavity from the nasal cavity. However, when there is palatal dysfunction, non nasal sounds become nasal, thus producing nasal inarticulate speech.

Nasality may be due to congenital conditions (cleft palate), to injuries following the removal of tonsils and adenoids, to inflammations (nose, pharynx or adjacent area), to tonsillitis, diphtheria, syphilis or tuberculosis, to tumor, to nervous conditions, to bulbar paralysis or to tic. Nasality causes the voice to become weak, flat or dull, and nonmelodious in quality.

or anatomic defects in the central nervous system. These include mental deficiency of various types, with or without gross neuropathology, congenital anomalies and diseases and injuries of various subcortical areas. Muscular incoordination of the vocal tract is part of the general incoordination.

As hearing is the means by which sounds are learned, articulation directed and inflection controlled, impairment of hearing is a most serious cause of impairment of speech. However, the mere coexistence of a defect in hearing and one in speech does not necessarily mean that defective hearing is always the cause of the defect in speech.

Some children whose hearing may be considered normal lack appreciation of certain combinations of tones to such a degree that they are not sure of the pronunciation of certain words. Often, for instance, they may not be able to hear sounds in high frequencies although they may hear sounds in low frequencies very well. Their speech may sound defective, and occasionally it may even predispose them to stuttering. The impairment in hearing may be slight, and yet a serious defect in speech may exist solely because of undesirable environmental factors, such as poor speech models, foreign language conflicts and emotional factors.

approaching twang characteristics, it causes a change in speech, making articulation difficult, besides bringing about tonal changes

The congenital condition of cleft palate, with its resultant cleft palate speech, is a pronounced cause of rhinolalia. A cleft of the palate may or may not be associated with a harelip. Both conditions are due to a failure of closure of the anteroposterior fissure between the two lateral halves of the roof of the mouth.

Dunning,¹ in discussing operative measures, says: "The cleft in the bone in the front of the mouth should be closed in the first few weeks, if the baby is doing well. The opening or split in the lip should be closed two or three weeks after the bone operation, if the baby is in good condition, and the palate should be repaired during the third or fourth year."

Obturator is contraindicated for children because they cannot be made to fit properly, on account of growth and anatomic changes. After operative measures, reeducational speech and voice treatment should be instituted, since the resonance, quality and articulation found in normal speech are more or less lacking in cleft palate speech.

The conditions grouped under the heading dysphonia consist of defects of voice due to organic or functional disorders of the vocal tract: trachyphonia, i.e., the common condition of hoarseness, which is often due to infiltration from diseased tonsils, adenoids or sinuses and which may appear in children as a diphtheritic sequel, functional disturbances, as exemplified by hysterical aphonia, and the many other conditions enumerated in the table. It is not my intention to elaborate on these conditions at the present time but rather to consider the important group that falls under the classification of dysphemia, or stuttering, and particularly the stutter-type child.

A misconception is still prevalent about the stutter-type child and his symptom, stuttering. Parents continually tell us that their child is quite well in every way, that he is bright at school, often being a class ahead for his age and that he has no particular physical complaint. Apparently the only thing wrong is that "he just cannot get the words out." He stutters, and they firmly believe that a few speech drills are all that is necessary to establish or reestablish the smooth flow of words. In most instances neither the parent nor the teacher is conscious of the fact that this is a special type of child. I mention this to emphasize the fact that when one is considering any form of human behavior, in health as well as in disease, the only intelligent and fruitful view is that of considering the organism or personality as a whole functioning unit. In accordance with this point of view, the symptom of stuttering should not be isolated but should rather be considered as an expression of the whole organism of a disintegrated individual.

I have designated the special type of personality with which I am dealing here the stutter type—a type whose condition consists of a definite correlation between the characteristic physical and the equally characteristic temperamental traits. However, it should be realized that individual variations are so numerous in the stutter type and that so many factors enter into the building up of his personality that only a careful study of his person as a whole demonstrates his status.

I shall deal first with the field of predisposition as a factor in the maldevelopment of the stutter-type child.

It has long been an acknowledged fact that a general predisposition toward emotional instability can be traced in the family of the stutter type. A study of over 1,000 patients who were treated in the National Hospital for Speech Disorders during the year 1935 showed that 40 per cent had stutterers in their immediate family. Over 50 per cent gave a definite history of emotional instability in the family.

A child of such a family does not necessarily inherit stuttering as such but belongs to the stutter type and inherits special neuropathic tendencies, a general instability of the nervous system which predisposes him to hesitating speech. This predisposition can often be readily observed, even by the noninitiated, by noticing the striking effects of a single speech effort in a stuttering child or adult. On examining the hands of such persons in the throes of spasmodic speech, one will often observe that the palms are drenched with perspiration. This abnormal functioning of the sweat glands is a visible index of the severe internal emotional turmoil that accompanies the speech act in the stutterer. Incidentally it serves as an excellent example of the unity which exists between the psyche and the soma, in sickness as in health.

Regarding the mechanism by which these manifestations occur, a frequent question and a most relevant one is: What special constitutional differences exist between the stutterer and the nonstutterer?

At present, among the different workers in the field there is an increasing unanimity that the one outstanding somatic finding is marked instability in the functioning of the vegetative nervous system, with special dysfunction of the vasomotor apparatus. It is a generally accepted view that most people in states of excitement demonstrate dominance of the sympathetic branch of the vegetative nervous system. Professor Seemann,² in a study of 260 stutterers, found an imbalance of the vegetative nervous system in 88 per cent of the subjects. Thirty-six per cent demonstrated sympathetic dominance, 18 per cent showed parasympathetic dominance, and 34 per cent showed evidences of increased tonus in segments of both branches of the vegetative nervous system, or amphotonia.

Another investigator³ found that of a hundred stutterers, 75 per cent showed extreme variations in their vegetative endocrine organization as follows: (1) atypical vasomotor functioning, 71 per cent, (2) atypical dextrose mobilization, 74 per cent. He further states that the frequent variations in the endocrine constitution among stutterers may be explained on the basis of an atypical vegetative organization. A striking indication of this lability is the marked dysfunction of the stutterer's vasomotor apparatus. As I have mentioned, his condition of hyperhidrosis is an outstanding symptom. However, one just as frequently finds dermatographia and acrocyanosis among his other anomalies. One may deduce from these facts and others that the most important finding, as far as the constitution of the stutterer is concerned, is a high degree of deviation in the functioning of the vegetative nervous system.

These deviations in the neurologic functioning of the stutter type are manifest in his disorganized muscular coordinations. These incoordinations may appear in any neuromuscular activity and in many psychomotor patterns, but the fundamental characteristic is a lack of

¹ Dunning, H. S. The Question of Cleft Lip and Cleft Palate. radio address, May 1936.

³ Szondi, L. quoted by Seemann.

rhythm in performance. In other words, the stutter-type person lacks harmony, he is out of tune both neurologically and emotionally and unequal to the strenuous tempo of life.

The psychic or emotional manifestations that correlate with the previously mentioned physical ones, producing the psychosomatic unity which is called the stutter type, include primitive emotional reactions such as morbid fear and anxiety, setting off the tendency to many hesitating acts.

As a consequence of these underlying affects, stutter-type persons are highly sensitive to all stimuli, so that they belong to the quick reacting group, whose frequency of impulse is high, resulting in strong intensity of reaction. They are in a chronic state of tension, which tends to lower the threshold of their excitability. This accounts for the fact that they get excited so easily and are prone to anticipatory anxiety. This psychomotor unity is expressed in the symptom stuttering. In other words, the neurotic functioning converts the psychic conflict into a physical symptom.

A theory that has been attracting much attention in recent years is that of cerebral dominance, and many investigations have been made from this approach. The proponents of this theory advocate as the cause of stuttering the confusion in dominance in the functioning of the cerebral hemispheres. There is no general agreement regarding this theory. On the affirmative side, it is asserted that stutterers are more frequently left handed or ambidextrous than normal speakers. On the other hand, the negative side contends that left-handedness, if present, may have no specific meaning, as left-handedness is commonly found with psychoneurosis, behavior disorders, epilepsy, squint, high blood pressure and other conditions. The question is still unsettled. In spite of the emphatic statements that have been made by both sides, a scientific impartial appraisal of the various arguments leads one to conclude that stuttering may or may not be directly related to left-handedness or manual reversal.⁴

I will now take up the next and perhaps the most important determinant of stuttering, namely, the early conditionings in the family, a family which, as is already known, is so heavily laden with emotional tension. The aforementioned vegetative-endocrine deviations are only the foundation. They are insufficient to produce the stutter type without the essential superstructure of the early familial conditionings. As Richmond⁵ says, "by the time the child reaches school the main channels in which his emotional life will flow have been fairly well marked out. His early experiences set the pace for his later attitudes and fear may have become a dominant factor in his dealing with reality." These early conditionings, being very important, may be elaborated on at great length. Only two major influences, however, will be mentioned. The first consists of the various and sundry expressions of aggression on the part of either parent, more commonly the mother. These aggressions are almost always disguised as love, overprotection or oversolicitude. The result is infantilization of the child, in which it reacts with various forms of fretfulness or protest, stuttering speech being one of the expressions of protest. Overdemonstrative love is just as bad as too little love during the period of early childhood, the two frequently springing from the same source.

Cases of overt parental rejection of the child are much less common, although they are probably more frequent than is generally believed. Overt parental rejection was vividly illustrated in the case of a person recently admitted to the clinic. This young woman, until the age of 23, when her mother died, was never allowed any personal freedom whatever. She was allowed no male companionship and was frequently disciplined in public. In the privacy of the home, persecution took the form of lectures, nagging and even physical punishment. This parental domination had continued since early childhood. The result was that at the age of 30 the patient had the appearance and showed the general attitude of an adolescent girl, physically and emotionally. She looked and behaved like a child, retarded in her normal development by the neurotic influences within the home.

To another group belong the cases in which stuttering appears during the early critical adjustments at school, as distinguished from those previously mentioned, in which infantile stuttering has already appeared during the disciplinary crises in home training. Stability or continuity in the home is essential to the well being of the child, who at best feels insecure in a world of adults in which the only form of security is parental love. The lack of adjustment to the school environment is aggravated if changes in the home life bring with them a constant shift of school environment.

This mechanism was well illustrated by one of our patients, a girl of 12 years, who stated that she had been to ten schools since the age of 6 years and that her parents had moved fourteen times, as far as she could remember. At home she was frequently scolded when she did not finish her chores in time. Her mother constantly threatened to put her back in public school if her speech did not improve in a hurry. Her general appearance was tense and fearful, she looked like a little old woman.

From the two examples given, one can appreciate the dire results of a home environment charged with parental neuroticism. Not enough consideration has been given to the extensiveness of this condition and its influence on the individual child in restricting the normal development of his personality.

The first case, that of the young woman who was so excessively disciplined, well illustrates parental aggression. Such aggression is a pathologic substitution for the normal state of indulgence. This normal state involves giving on the part of the parents and is accepted by the child as his natural birthright—as indeed it is, for without it he would perish—and can be covered by one word, love.

After the child has experienced the satisfaction of the many indulgences, there then comes a phase involving training in giving up privileges in the interest of socialization. This can be termed the phase of deprivation. It means the child's gradual surrender of his unlimited infantile privileges, an imposition which he receives with great reluctance and loud protest. Even under the most favorable conditions this constitutes a critical period in the child's life. It is therefore easy to realize what emotional disturbances may occur during this trying period. Thus, a great many children attach strong emotional attitudes to difficult problems and situations, so that when confronted with similar or simulating conditions they show morbid anxiety or fear.

The consequence is an ever-growing neurotic fear in social situations, which makes adjustment increasingly

difficult. Hence, if the setting is neurotic, such a medium or background undoubtedly serves as the incubation stage for the future neurosis.

SUMMARY

An analysis of 2,203 patients in a year (1936) applying for treatment at the Medical-Social Clinic showed that about 50 per cent suffered from dysphemia (stuttering) and that the rest suffered from various forms of voice and articulatory conditions.

While, as far as the individual sufferer is concerned, the defects of articulation and phonation are equal in importance to stuttering, the complexity of the problem of stuttering speech makes it of far more importance from a therapeutic point of view.

In the approach to this complex problem, the stuttering child is classified in a special group. He is viewed as a nervously agitated organism demonstrating strong excitation and a tendency to quick interruption or inhibition and having a high emotional tone.⁶ Because of this peculiar functioning of the nervous system, the stutter-type child may demonstrate his hesitating performances not only in speech but in many other forms of psychomotor activity. However, as the neuromuscular coordinations involved in speaking are of a highly complex and delicately balanced nature and since speech is so necessary for normal social adjustment, the involvement of the speech faculty in the stutter-type syndrome makes stuttering in speech a far more serious problem than chronic hesitation in other muscular activities.

Because of the high emotional tone of the stutter-type child, stuttering speech, with its usual history of humiliation, failures and frustrations, eventually leads to the development of an anxiety state regarding speech and social maladjustment involving the total personality of the child.

Stuttering has been viewed at the National Hospital for Speech Disorders primarily as a physical symptom of psychic conflict, with the high emotional energy of the stutterer directed toward a fear which disintegrates his entire personality, and the treatment has been arranged in the form of a composite therapy of a medical, social, psychiatric and psychologic nature, directed toward the tranquilization, organization and adjustment of the personality.

As the stutter-type child's difficulty is one of social adjustment, his personality problems are worked out in a group medium, directed toward the integration and organization of his personality, so that he may make adequate adjustment to home, school and juvenile social environments.

Since the neurologic conditions inherent in the stutter-type child's neuropathic diathesis are aggravated by tensions arising from parental neuroticism and lack of harmony in the preschool home environment, a parent group has been formed for the mothers to facilitate the making of home adjustments. Under proper guidance, mothers receive an insight into child psychology and the importance of harmony in the home. This has resulted in the removal of many disturbing causal factors.

CONCLUSION

Having demonstrated the prime importance of preschool environmental influences, may I point out the urgent necessity for prophylaxis in the form of wholesome parent-child relations. Only recently, Dr Ber-

nard Sachs⁷ aptly epitomized the importance of early familial influences. "The influence of the home is paramount."

Parents must always remember that their own actions make a far deeper impression on the child than any sermons which they may choose to launch. Which means that in order to reach the child one must first reach the parent.

In doing this, the pediatrician has a most important role. His cooperation in establishing the proper parent-child relation is of the utmost importance to the speech pathologist, whose success in fostering robust straightforward development in the stutter-type child depends on a tranquil, harmonious home environment. By the application of a few simple principles of mental hygiene, previously mentioned, the pediatrician can play a most valuable part in effecting adjustments of far-reaching importance to the individual and to the community.

TREATMENT OF ULCERATIVE COLITIS
WITH ALUMINUM HYDROXIDE
AND KAOLIN

JAMES B. EYERLY, M.D.
AND
HERBERT C. BREUHAUS, M.D.
CHICAGO

One of the oldest remedies brought down to present-day medicine is kaolin (aluminum silicate). It is one of the chief products of the erosion of igneous rock and therefore is a common constituent of many soils and is classified as a silicious earth. Rich deposits of high grade kaolin are found in parts of the United States and also in the Orient, where it is mined chiefly for use in pottery and was used very effectively in the treatment of Asiatic cholera many centuries ago.

Both Walker¹ and Braafladt² were impressed by the great usefulness of this product in the treatment of the 1919 epidemic of cholera in China. In giving it both by mouth and by rectum it proved to be one of their most useful aids in bringing about a great decrease in mortality. Walker in discussing the rationale of kaolin concluded that its action was twofold. First, there is a mechanical action, because large numbers of bacilli are enclosed and carried off but are not killed. Second, by adsorption the kaolin takes up toxins. Braafladt also studied the action of kaolin in both normal and pathologic conditions. He concluded that it carries down large numbers of bacteria from fluid mediums if it is kept in motion. The latter consideration is important because kaolin, although it has some colloidal activity, has a tendency to settle out of a liquid medium and thus its large surface area for adsorptive purposes is lost. When kaolin settles out from suspension, a firm, tenacious, claylike mass results (bolus alba) which may lead to serious fecal impaction in the rectum. He also found that various pathologic bacterial toxins were neutralized. He emphasized the proteolytic action of these bacteria and observed that when kaolin is taken by mouth for a period of from ten to thirty days in doses of from 1 to 2 ounces (30 to 60 Gm.) a change in

flora to an aciduric type may be accomplished. B welchii was practically eliminated from the stools in these experiments. It is interesting to note that Dragstedt found kaolin as useful as a high lactose diet in preventing thyroparathyroidectomized dogs from going into tetany.

Kaolin is a common constituent of many soothing powders, chiefly by virtue of its inert, highly adsorptive property. Hektoen and Rappaport³ found it useful in cases of diphtheria, applying the dry powder to the nose and throat at intervals of two hours. They explained its action as a physical one in that practically all pathogenic bacteria were removed in from three to four days. In severe pharyngitis they obtained excellent results by having their patients swallow one-third teaspoonful four or five times per hour during the day.

Aluminum hydroxide is somewhat similar to kaolin but has greater colloidal activity. It settles out of suspension less readily and forms a light viscid gel. Under certain conditions it is capable of acting as either a weak acid or a weak base, this property alone has made it popular in the treatment of peptic ulcer. It also has a moderate astringent action and causes a mild dryness and puckering of the mucous membranes of the mouth when taken orally. Because of the increased colloidal and astringent action, its value as an addition to kaolin readily becomes apparent.

Neuman⁴ in 1914 was one of the first to report the use of aluminum hydroxide in bringing about a more rapid line of demarcation and healing in gangrene. He accredited this to its protective power and ability to neutralize acids as well as other toxic products. Zuverkalov and Salomkin⁵ found that hog cholera virus might be adsorbed by aluminum hydroxide from blood and urine at a p_H of five. By iso-electric precipitation of the protein, the virus could be precipitated but the supernatant fluid also contained the virus. They found the adsorption to be reversible in that the virus could be eluted with phosphate and aminoacetic acid (glycine). Complete adsorption could not be obtained when up to 2 per cent aluminum hydroxide was used.

Clifton⁶ reports that staphylococcus bacteriophage can readily be adsorbed by aluminum hydroxide. This too could be eluted by using a secondary ammonium phosphate solution.

Differences in the adsorption of diphtheria toxins by aluminum hydroxide are recognized. Schmidt⁷ used purified diphtheria vaccines of the same titer and noted that they were adsorbed in varying degrees by the same amount of aluminum hydroxide. Roughly, the adsorbability of the vaccine was related to the nitrogen content of the salt-free preparation, but different adsorbability was found in samples of similar nitrogen content.

Knowing that there was little doubt about the ability of aluminum hydroxide to adsorb toxins, we were interested in studying its neutralizing effect. When 110 minimum lethal doses of a stock diphtheria toxin was mixed with 5 cc. of a 3 per cent aluminum hydroxide suspension and shaken thoroughly and then injected into a guinea-pig, the animal was sick on the fourth day and recovered. Any larger amount of this toxin resulted in death of the animal within twenty-four hours. While this apparent protective action may have been due to

the slowing of absorption of toxin, it may also have resulted in part from segregation of the toxin by adsorption.

The varying ability of this chemical to adsorb diphtheria toxin may be just as applicable to toxins from other sources and its neutralizing capacity thus also vary. When one deals with a toxin in the alimentary tract the situation is entirely different from that in an enclosed body cavity and, even though the toxin is not neutralized, anything that would adsorb or prevent its absorption by the body until it is eliminated would be beneficial.

It is important that the kaolin and aluminum hydroxide be as chemically pure as possible. Any impurity changes colloidal activity and may lead to disappointing results. Small quantities of alkali cause kaolin suspensions to settle out into a firm mass. On the other hand, alkali affects the mixture of aluminum hydroxide and kaolin in an opposite manner and gives a greater bulk with a firmer gel.⁸

The normal flora of the colon is mildly aciduric and relatively few of the proteolytic or gram-positive organisms are seen. When proteolytic organisms preponderate and the normal intestinal action is disturbed, the reestablishment of an aciduric flora is often difficult. It seemed worth while to try aluminum hydroxide and kaolin for this purpose. Braafladt stated that by feeding kaolin alone he could remove the putrefactive organisms and produce an aciduric flora. Neither we nor Swalm⁹ were able to produce this change, though the latter was able to establish an acidophilus culture with a mixture of kaolin and aluminum hydroxide. In several feeding experiments on dogs and rats we were never able to reduce the gram-positive organisms below 20 per cent in rats and 50 per cent in dogs.

Swalm used a kaolin-alumina mixture in treating many gastro-intestinal disorders and found that 86 per cent were definitely improved by addition of this medication to the general therapy. He stressed its local action in the lumen of the stomach and intestine through its mildly astringent and adsorptive properties and believes it to be most useful in hypermotile states.

TOXICITY OF ALUMINUM

Aluminum in minute quantities is found normally in the tissues of animals. There is little evidence that any harm results in the amounts in which it is likely to be consumed. Without question some of the more soluble forms, such as alum or aluminum chloride, are quite toxic and even fatal when taken in large quantities. Underhill and Peterman,¹⁰ using biscuits made with alum baking powder, found that the metal was readily absorbed and excreted in the bile and urine. When given in large doses it is chiefly stored in the liver, spleen, brain and thyroid gland. The same authors injected aluminum chloride and sulfate into rabbits and rats, producing changes similar to lead poisoning.

Seibert and Wells¹¹ fed large amounts of the various forms of aluminum to rabbits and produced varying degrees of toxic changes in all animals. They concluded

The strongest evidence, however, that the feeding of aluminum compounds in any form, including that supposed to be so insoluble and inert as aluminum hydroxide, may be harmful

lies in the results obtained in the feeding experiments with large single doses of aluminum compounds. Quick responses such as decreases from two to three million in the number of erythrocytes and of as much as 20 per cent in the hemoglobin were noted in 7 day or two following the injection of large doses of aluminum in the form of metallic aluminum and the granular, insoluble aluminum hydroxide.

In spite of these results we feel, as others have shown,¹² that small doses of aluminum, especially of such an insoluble form as aluminum hydroxide and kaolin, will result in no harm. Relatively large doses of both these compounds when fed to dogs by stomach tube over a period of three months produced no untoward results. Aluminum hydroxide has been used for several years in the treatment of peptic ulcer without any evidence of toxicity. In Swalm's sixty-five cases treated with a kaolin-alumina mixture, no harmful results were noted.

To determine the effects of relatively large doses of kaolin and aluminum hydroxide when taken by mouth, two dogs were fed 2 ounces of these substances by stomach tube for six days each week over a period of three months. Dog 1 was a normal appearing male and weighed 26½ pounds at the beginning of the experiment. It was given 2 ounces of kaolin suspension between 10 and 11 each morning for six mornings a week over a period of three months. The diet consisted of a single feeding of scraps given about 12 noon. At no time was there any evidence of ill health, but occasionally a rather firm chalky stool was passed. After twelve weeks the animal had gained one-half pound and was in excellent condition. At this time the dog was killed and a thorough postmortem examination showed no changes worthy of note.

Dog 2 was a normal appearing adult male and weighed 25 pounds at the beginning of the experiment. It was given 2 ounces of a 3 per cent aluminum hydroxide suspension and managed in the same manner as dog 1. This dog also remained normal in behavior and appearance during the three months. It lost one-half pound but at all times passed normal stools. At autopsy no change in any tissues or organs was found except two small roundworms in the first part of the ileum.

Histologic examination of the liver, kidney, spleen, brain, heart, lungs, adrenals, stomach, small and large intestines and mesenteric lymph nodes of both these animals showed no changes worthy of note. These were stray dogs and had been in the laboratory only a few days before the experiments were begun. Such animals usually gain a few pounds when confined and put on a diet of scraps. The fact that they practically maintained their original weight is significant. Since no pathologic changes could be found, it seems quite probable that the administration of aluminum hydroxide and kaolin reduced the effectiveness of the digestive juices.

METHOD OF ADMINISTRATION

It has been customary to give kaolin or a mixture of kaolin and aluminum orally. Except for lesions in the upper gastro-intestinal tract, this method has certain limitations. Walker and Braafldt found that a combination of both oral and rectal administration was most effective. When the patient was sufficiently recovered, they gave kaolin only by mouth. Walker realized the possibility that kaolin might also take up the digestive juices and found that rennin would be adsorbed when it was filtered through a kaolin bed. Swalm also

considers this factor and advises that such a mixture should not be given by mouth over too long a period of time.

In ulcerative colitis there is a raw ulcerating mucous membrane, and thus to obtain the maximum benefit from kaolin and aluminum hydroxide we give it only by rectal retention. First, the colon is cleansed with a pint of warm water. In one hour this is followed by a retention enema consisting of a 3 to 5 ounce (60 to 150 Gm) mixture of kaolin and aluminum hydroxide in from 3 to 5 ounces (90 to 150 cc) of warm distilled water. The patient is instructed to retain this as long as there is no discomfort. Usually one retention a day is sufficient, but occasionally two are given. In this manner, larger doses of the mixture can be brought into direct contact with the inflamed mucous membrane without previous admixture with food and digestive juices.

REPORT OF CASES

CASE 1—A white woman aged 35, entered the hospital Aug 16 1934, complaining of intermittent diarrhea and blood in the stools for six years. There were from four to twenty stools in each twenty-four hour period. There was no abdominal pain but considerable tenesmus. The patient had lost 65 pounds (29.5 Kg). The past history was essentially negative except for the usual childhood diseases. The tonsils were removed at the age of 18 years.

The patient was anemic and emaciated. The abdominal muscles were relaxed, the descending colon was palpable, firm and sensitive. A soft systolic murmur was heard near the apex, otherwise there were no physical observations of note.

The laboratory examination revealed hemoglobin 57 per cent, red blood cells 3,600,000, white blood cells 9,700. The urine was normal. The stools were liquid and contained gross blood, clumps of leukocytes and considerable mucus. No parasites were found in either freshly examined or cultured specimens. A good growth of gram-positive diplococci was obtained in the blood agar culture.

An Ewald test meal showed 50 points of free hydrochloric acid and 75 points of total acidity.

The proctoscope was inserted without difficulty. The mucous membrane was edematous, dark red and covered with a dirty gray tenacious exudate which, when removed, uncovered a raw, bleeding surface. No distinct ulcers were seen.

A therapeutic test with carbarsone was given without benefit. Acriflavine 1 3,000 irrigations were used each day for some weeks without improvement. A 15 per cent bismuth subgallate suspension in mucilage of acacia as a retention enema was given for three weeks without change. An autogenous vaccine made from the stools was given for six weeks without benefit.

The patient was then given aluminum hydroxide and kaolin retentions once a day. Within two weeks a definite improvement was noted. The retentions were continued for six months, at which time she had gained 40 pounds (18 Kg). The retentions were discontinued and the patient is continuing to pass on an average two normal soft formed stools each day. Proctoscopic and fluoroscopic examinations reveal a normal appearing membrane and the presence of the normal haustral markings.

CASE 2—A white man, aged 21, entered the hospital June 3, 1935, because of a severe diarrhea during the previous four years. In that time as many as ten and no less than four liquid stools were passed daily. Approximately two years before entrance his physician prescribed a bland diet, opium and bed rest. Fresh stools were repeatedly examined and cultured but no amebae, ova or parasites were found. Vaccines made from cultures of the nasopharynx and stools were given every five days for four months. The predominant organism in the stool was a very highly hemolytic colon bacillus with this were two types of *Streptococcus viridans* one which formed short chains similar to diplococci, and a few hemolytic streptococci. Acetarsone was given without benefit.

During the last year previous to entrance the patient's weight had increased to normal. He was however, able only to be about in a wheel chair. Such effort as walking one block was followed by increased diarrhea.

¹² Einsel, I. H., Adams, W. L., and Myers, V. C. *Am J Digest Dis & Nutrition* 1: 513-516 (Sept.) 1934.

General physical examination was essentially normal. The laboratory examination revealed hemoglobin 78 per cent, red blood cells 4,100,000, white blood cells 11,200. The urine was normal. The stools gave a strongly positive occult blood reaction and contained numerous leukocytes and considerable mucus. The fresh specimens were again examined and cultures were taken but no parasites were found.

On proctoscopic examination the mucosa was friable, bled easily and had a beefy red appearance without frank ulceration. Many edematous areas from 3 to 5 mm in diameter and a moderate amount of stringy, blood-tinged mucus were seen.

A barium sulfate enema showed a moderately decreased lumen and an absence of haustral markings.

Aluminum hydroxide and kaolin retentions were taken once daily for one year. In that time the patient had resumed his previous activities, such as horseback riding and hiking, without disturbed bowel function. The rectal mucosa now appears normal and haustral markings are again present.

CASE 3—A white man, aged 28, who entered the hospital July 15, 1935, had always experienced good health until five years before, when he began having generalized abdominal cramping and diarrhea, passing from twelve to fifteen watery stools each twenty-four hours. Visible blood was present in most specimens. After various methods of treatment, including hydrotherapy, vaccine injections and colonic irrigations, the patient stated that there was some improvement in that the stools were reduced to from six to eight daily.

The patient had had the usual childhood diseases and pneumonia in early youth. The tonsils and adenoids had been removed. A rectal ulcer was treated surgically four years previous to his entering the hospital.

On physical examination the patient appeared anemic and somewhat emaciated. There was tenderness over the descending colon area. Otherwise there were no observations of note.

The laboratory examination revealed hemoglobin 50 per cent, red blood cells 3,900,000, white blood cells 11,000. The urine was normal. The stools were liquid and contained gross blood, microscopic examination revealed many large masses of leukocytes. No parasites were found in either fresh or cultured specimens. On culture on endo and blood agar plates a good growth of *B. coli*, *Streptococcus viridans* and a nonhemolytic *streptococcus* was found.

An Ewald test meal showed free hydrochloric acid 70 points, total acidity 85 points.

The proctoscope was inserted with difficulty owing to a markedly contracted rectum. The mucous membrane was edematous, was covered with a purulent exudate and bled readily wherever touched.

A barium sulfate enema revealed a marked constriction throughout the colon except in the cecal and ascending regions.

The usual diet was prescribed. A therapeutic test with carbarsone and emetine produced no change. A 15 per cent bismuth subgallate suspension in mucilage of acacia was used as a retention without success. Acriflavine 1 3,000 irrigations failed to improve the condition. Aluminum hydroxide and kaolin orally produced no change, but when given by retentions in the usual manner caused a marked improvement after three weeks. In eight weeks the patient gained 30 pounds (13.6 Kg.) and the only stool passed each day was the one expelled with the cleansing enema which preceded the aluminum hydroxide and kaolin retention. The proctoscopic examination revealed a mucous membrane slightly more injected than normal. The fluoroscopic examination showed the lumen of the colon to be of normal width.

CASE 4—A white man, aged 66, had been in poor health for some time before entering the hospital, Oct. 9, 1935, with complete urinary obstruction. An emergency cystotomy was performed. At that time the blood chemistry showed total nonprotein nitrogen 97.6, urea nitrogen 66.6, creatinine 3.9. He was given a transfusion of 460 cc. of whole blood, and twenty days later a suprapubic prostatectomy was performed. At that time the blood chemistry showed total nonprotein nitrogen 53.3, urea nitrogen 22.8, creatinine 1.7. The hemoglobin had increased from 60 per cent to 70 per cent, the red blood cells from 3,110,000 to 3,950,000, and his condition in general was greatly improved.

Three days after the prostatectomy he began to pass frequent liquid stools containing macroscopic blood, clumps of leukocytes and mucus. Methylene blue was injected into the bladder but none was recovered in the stools. On rectal examination there

was no opening through the rectal wall. Proctoscopic examination up to the rectosigmoid junction revealed a red edematous mucous membrane covered with much mucus. The mucous membrane bled readily wherever touched, no distinct ulcerations were seen. Several fresh specimens were examined and cultured on liver serum but no amebas were found. Culture on blood agar yielded an abundant growth of *Streptococcus viridans*.

The patient was given retentions of aluminum hydroxide and kaolin once a day. After five days the medication was discontinued. The stools were formed and microscopically negative.

CASE 5—A white woman, aged 34, entered the hospital May 28, 1936, complaining of diarrhea for three months, passing from four to six liquid stools containing gross blood each day. Abdominal cramping and rectal pain accompanied these movements. The weight loss was 12 pounds (5.4 Kg.).

The patient had a similar illness six years before, at which time she was a bed patient for three months. At that time treatment consisted of a nonirritating high caloric diet, sedatives and bismuth subgallate in mucilage of acacia. She then remained in good health until the present recurrence. The tonsils had been removed at an early age. There had been no other illness of note except the usual childhood diseases.

The patient appeared ill and anemic. The temperature was 101 F. There was tenderness over the region of the colon and muscle resistance in the lower left abdomen. General physical examination otherwise gave normal results.

The laboratory examination revealed hemoglobin 63 per cent, red blood cells 3,730,000, white blood cells 12,600. The urine was normal. The stools were liquid and contained gross blood, clumps of leukocytes and much mucus. Fresh specimens were repeatedly examined and cultures were taken but no parasites were found. Culture on blood agar yielded chiefly nonhemolytic *B. coli* and occasional colonies of *Streptococcus viridans*.

Proctoscopic examination revealed a narrow lumen and highly inflamed mucous membrane covered with mucus which, when removed with a cotton swab, left a raw bleeding surface.

A barium sulfate enema was accompanied by considerable pain and spasm. The diameter of the colon was decreased and the haustral markings were absent.

The patient's usual nonirritating, high caloric diet was continued. A therapeutic test for two weeks with emetine and vioform failed to improve the condition. Aluminum hydroxide and kaolin retentions were given in the usual manner. After eight weeks the temperature has remained normal. Gross blood is no longer present in the specimens. An average of two stools are passed each twenty-four hours. A gain in weight has resulted and a marked general improvement is seen in the patient.

CASE 6—A white woman, aged 29, entered the hospital Jan. 22, 1936, complaining of diarrhea for one year, passing from four to six liquid stools containing gross blood each day. She had considerable abdominal distress.

The past history was negative except for the usual childhood diseases and tonsillectomy during her youth.

Physical examination was essentially normal except that the patient appeared anemic.

The laboratory examination revealed hemoglobin 71 per cent, red blood cells 4,000,000, white blood cells 9,450. The urine was normal. The stools were liquid, they contained gross blood and leukocytes in clumps. Examination of fresh and cultured specimens revealed no parasites. On endo and blood agar plates an abundant growth of nonhemolytic *B. coli* was obtained.

An Ewald test meal showed 25 points of free hydrochloric acid and 55 points of total acidity.

The rectal mucous membrane was edematous and many shallow ulcers from 1 to 3 mm. in diameter were seen. When the tenacious gray exudate was removed, a raw bleeding surface remained.

A barium sulfate enema showed a decrease both in the diameter of the descending colon and in the haustral markings.

A therapeutic test with carbarsone produced no change. Aluminum hydroxide and kaolin were given. After eight weeks the temperature was normal and a slight tendency to constipation existed. One month later she had gained 12 pounds (5.4 Kg.) and was passing one normal stool daily. Retentions were discontinued. Two months later there was a recurrence of diarrhea. At that time the rectal mucosa was found to be considerably injected but no ulcers were seen. Retentions were

resumed for six weeks. At present the patient passes one or two formed stools without gross blood each day. The appetite is excellent, a gain in weight is resulting and the condition in general is greatly improved.

COMMENT

In a review of these cases it is noted that the therapy employed is not unlike the various methods generally found useful in treating ulcerative colitis.

The diet must be of high caloric, nonirritating type and contain all vitamins necessary for normal health. Opium in some form is frequently used in the early stages if pain and excessive diarrhea are present. A consistent program carried out intelligently is essential if such cases are to be cured.

CONCLUSIONS

Investigation by others and our clinical study support the belief that the treatment of ulcerative colitis by aluminum hydroxide and kaolin mixture is rational.

The adsorption of bacteria and their products reduces irritation and decreases the absorption of toxins.

The astringent action lessens absorption and the transudate from the inflamed surfaces is diminished.

It is not toxic.

There is no admixture with food and digestive juices.

A neutral reaction in the lumen of the bowel is preserved.

No bolus or impaction formation occurs with moderate care.

ANTEPARTUM CARE

ITS ADVANTAGES AND ITS SHORTCOMINGS

ABRAHAM B. TAMIS, M.D.

AND

JACOB CLAHR, M.D.

Assistant Attending Obstetricians, Morrisania City Hospital

NEW YORK

The continued high rate of preventable maternal and fetal deaths has challenged the medical profession both here and abroad. It is to the credit of organized medicine that the facts are being squarely faced. Every phase of maternal care from the time of conception to the puerperal state has been subjected to investigation. Contraceptive technic, abortion, antepartum care, management of the delivery, the postpartum period, the nursery, all are being carefully analyzed by the best trained specialists in this field. No doubt, definite benefits will be derived from these studies.

We have been particularly interested in the antepartum clinic since the inception of Morrisania City Hospital in 1929 and systematically collected and studied the clinic data in 1934. A brief description of the clinic is essential for a proper interpretation of our data. The outpatient department of Morrisania City Hospital (a municipal hospital) accepts only indigent patients irrespective of race, color or creed. The inpatient service accepts all emergency cases brought in by the public ambulance, and cases transferred from other municipal institutions. The antepartum clinic is under the immediate supervision of the obstetric attending staff assisted by clinic physicians. The intern staff takes little part in the management of the clinic, thus leaving the entire responsibility of the conduct of the

clinic to doctors well versed in the physiologic and pathologic aspects of pregnancy. This plan has proved to be of distinct advantage to the patient.

The history, physical examination, blood pressure and pelvic measurements are all taken by a physician. A laboratory technician is available for the immediate examination of the urine. A blood Wassermann and a Kahn test are done in each case. Every patient is seen by the dentist and necessary dental care arranged for. Consultations with other specialty clinics are encouraged. Roentgenograms of the abdomen and of the pelvis are taken for suspected malpositions, multiplicity, pelvic contractions or cephalopelvic disproportion.

Following the initial examination the patient is given a pamphlet entitled "The Parents' Book," distributed by the New York State Department of Health. It describes in a clear and concise manner matters of particular interest to expectant mothers and emphasizes the danger signals of pregnancy.

Patients requiring closer observation because of some abnormality are instructed to attend the clinic rather frequently. The normal antepartum patients report once monthly before the seventh month of gestation, every two to three weeks in the seventh and eighth months, and each week in the ninth month.

Between Feb. 1, 1934, and Jan. 31, 1935, 1,009 patients registered in the antepartum clinic of the Morrisania City Hospital. A record was kept of the time of registration, number and frequency of clinic visits, and of any and all abnormalities. Following the delivery, the charts of both mother and baby were reviewed. Notations were made concerning the type and duration of labor, condition of the baby, and the clinical course of the mother during the immediate puerperium. The facts thus obtained comprise the material for this report.

It is interesting to note that, despite the gratuitous nature of this service, not one patient applied for antepartum care before the sixth month of gestation. The majority, 781 (67 per cent), registered in the sixth and seventh months, 264 (26 per cent) applied in the eighth month, and ninety-four (7 per cent) in the ninth month.

If the recommendation of the Children's Bureau of the Department of Labor that the first visit to the clinic or physician be made at or before the fifth calendar month of gestation is accepted, technically speaking none of our antepartum cases received adequate antepartum care. While we appreciate the usefulness of this definition from a statistical standpoint, it has been our experience that where registration was delayed to the fifth month of gestation no additional hazards to mother and baby resulted when the patient registered in the sixth and seventh months of pregnancy, except in the presence of a syphilitic infection.

In order to evaluate our antepartum service, therefore, we qualified those patients who registered in the sixth and seventh months of pregnancy and revisited the clinic when requested as having received adequate antepartum care. With this as a yardstick, only 499 of the 1,009 registered women actually obtained adequate antepartum care.

Very few patients, indeed, had any idea of the significance of the antepartum examination. It is surprising how many of the late registrants were aware of having had toxemia in previous pregnancies. Most of our patients were under the impression that registration in the antepartum clinic was a prerequisite for later hospitalization. In applying for antepartum care, their

main object was to comply with this imaginary regulation. Usually this was done as close to term as possible.

A considerable amount of effort and money has been and is still being expended to educate the public to seek professional advice during the earliest months of gestation. Does antepartum care warrant the expenditure of so much effort? Is antepartum care being over-emphasized? We shall endeavor to answer these questions by considering what defects were found in the course of our examination and the influence these abnormalities had on the health of mother and baby.

In our study 247 abnormalities were detected in 1 009 antepartum cases, approximately one defect to every four patients. These are enumerated in table 1. Toxemia of pregnancy, breech presentations and contracted pelvis were the most common observations. Next in frequency were cardiac disease and syphilis. Among the "other defects" listed in the table are anemias, multiple pregnancy, monstrosities, pyelitis and extra-uterine masses.

post partum she suddenly experienced a convulsion. The other patient had a rise in blood pressure in the seventh month of pregnancy to 150/100 and a 3 plus albuminuria. She was immediately hospitalized but within a few hours went into a convulsion. The blood pressure rose to 200/110, the urine contained 4 plus albumin and granular casts, and the patient became edematous. Labor set in spontaneously with some external bleeding due to a partial separation of the placenta, and the woman was delivered of a stillbirth.

The evidence indicates, then, that good antepartum care will not prevent eclampsia in every instance. In Adair's report,¹ adequate antepartum care was received by 12 per cent of the women whose deaths could be traced directly to toxemia of pregnancy. These deaths are doubtless due to the severe underlying pathologic condition found in such fulminating cases.

On the other hand, no one can question the value of early recognition of toxemia and immediate hospitalization so that proper measures for combating the toxemia

TABLE 1—Antepartum Defects, Mode of Delivery, Maternal and Fetal Mortality

TOXEMIA OF PREGNANCY

A total of fifty-two cases of late toxemia were seen in the clinic during the year investigated. Approximately one in every twenty registered patients showed some form of toxemia.

The most common type was the low reserve kidney. These patients were originally admitted with normal urines and blood pressures but, in the terminal month of gestation, developed a mild hypertension and slight albuminuria with or without edema. Labor was induced in four patients. The lack of antepartum care in this group apparently exerted no influence on the outcome for mother and baby, there being no maternal deaths and one neonatal death, which followed a forceps delivery.

Of the thirteen patients with eclampsism, only five had adequate antepartum care. Three patients developed convulsions. Of these, two had attended the clinic quite regularly. Both were white primiparas with normal blood pressures and normal urines on admission to the clinic. The first progressed normally up to the ninth month of gestation and then suddenly developed a hypertension of 180/130. Labor was induced successfully with castor oil and quinine and the patient was delivered spontaneously of a live baby. Nine hours

may be instituted. These measures in most cases will prevent further extension of the disease. Persistent headache, blurring of vision, severe epigastric distress, presence of edema, and inordinate gain in weight should immediately warn the obstetrician of impending danger. Stander's rule that all antepartum patients with a systolic pressure of 150 mm. or more of mercury be hospitalized is a very good rule. Even more significant, in our opinion, is a rise in the diastolic pressure to 100 mm. of mercury.

The need for an active social service staff is best exemplified in the care of toxemia patients. If the patient does not enter the hospital when requested, the next day the social service makes a home visit. In one case we enrolled the service of the police to see that the patient reached the hospital. This vigilance no doubt enabled more of our preeclamptic patients to receive early treatment, thus preventing in many instances the occurrence of convulsions.

BREECH PRESENTATIONS

While the blood pressure and urinalysis are regularly observed on each antepartum visit, the abdominal examination is too often neglected. The initial abdominal

1 Adair, F. L. Maternal, Fetal and Neonatal Morbidity and Mortality. *Am. J. Obst. & Gynec.* 29: 384 (March) 1935.

examination does not disclose all the information obtainable by this procedure, especially if performed prior to the seventh month. We reexamine all cases in the eighth month and again in the ninth month. By so doing, very few abnormalities of presentation, multiplicity, hydramnios, monstrosity, uterine fibroid, extra-uterine masses and cephalopelvic disproportion escape observation.

A problem of particular interest to us pertained to breech presentation. The diagnosis could be readily established by palpation and by x-ray examination. The malpresentation could be corrected in many instances provided it was detected before the presenting part became engaged or the fetus grew too large to make the turn. Statistics indicate that the vertex mechanism of delivery is fraught with far less danger to the infant than the breech mechanism. Our figures show a fetal mortality of 15 per cent in breech deliveries (twins and prematures excluded) as compared to a 2.6 per cent mortality in vertex presentation. Because of the more favorable outlook for the baby, we believe that attempts should be made in the antepartum period to convert every breech to a vertex presentation by means of external version.

Spontaneous version often occurs before the eighth month of gestation and sometimes even later. Therefore we reserve this manipulation to the eighth and ninth months of pregnancy. The maneuver of version is amply described in all the standard textbooks on obstetrics, and repetition here is superfluous. Version was successfully performed in thirty-one instances. On several occasions a recurrence of the malpresentation took place. However, we found that once an external version was performed it was always possible to repeat the procedure provided the recurrence was detected within a short period. Our patients returned each week until we were convinced that the vertex remained fixed at the lower pole. As shown in the table, all these patients were delivered spontaneously of living children except in one instance. In this case the fetal heart was not heard before birth. The cause of this fetal death was not determined.

Of the twenty babies that were delivered as breech presentations, fifteen were overlooked in the clinic and five could not be converted. This failure to convert was due to a tonic uterus, thick abdominal wall, oversized fetus, oligohydramnios, engagement of the breech, or lack of cooperation on the part of the patient. There were two fetal deaths in this group (prematures excluded).

CONTRACTED PELVIS

The classic monograph on the female pelvis by Caldwell and Moloy² was published shortly before the beginning of this study on antepartum care. From the very outset, therefore, we attempted to establish certain measurements by means of which the anatomic type of pelvis could be gaged without recourse to the x-rays. This proved to be no simple task, particularly because, as Caldwell, Moloy and Desopo showed in a later paper,³ many patients failed to exhibit a "pure" type of pelvis. Instead of a clear cut gynecoid, android or anthropoid pelvis, one was more apt to find various admixtures of the pelvic architecture, thus making it well-nigh impossible to make a correct anatomic diagnosis clinically.

Nevertheless certain very pertinent facts about the pelvis can be determined by palpation and mensuration. We agree with Schumann⁴ that all the external dimensions bear little or no relationship to the actual size of the pelvic inlet. We feel that the interspinous, intercrural, bitrochanteric and external conjugate measurements should be omitted from pelvic mensuration. More attention should be focused on ascertaining the height and inclination of the symphysis pubis, the subpubic angle, depth of the pelvis, the bischial dimension of the outlet, the diagonal conjugate, the contour of the sacrum and terminal coccyx, and the length of the sacrospinous ligament. The sum total of these observations will yield a fairly comprehensive idea of the pelvic capacity and its configuration.

The most significant measurement of the pelvis is the true conjugate. While the normal true conjugate (11 cm or more) does not predetermine an uncomplicated delivery, a narrow true conjugate (10 cm or less) promptly raises the question of permitting an unengaged or partially engaged vertex to withstand the stresses of vaginal delivery.

The usual method of estimating the true conjugate from the diagonal conjugate was often found to be erroneous because too little consideration was given to the inclination of the symphysis pubis. This was recently emphasized by Garnett and Jacobs.⁵ To obviate such errors we referred for x-ray examination all patients in whom the diagonal conjugate was under 12 cm, using the technic described by Weitzner.⁶ This method is easily performed, requires no expensive apparatus, and is accurate to within 0.2 cm.

For practical purposes we considered a pelvis as contracted when the true conjugate was found to be 10 cm or less. Fifty-two such contractions were found.

In this series one mother died of peritonitis following a repeat cesarean section and repair of an incisional hernia. The infective agent, *Staphylococcus aureus*, probably originated from the hernial repair. Three babies died as the result of instrumental trauma.

The outlook for mother and baby in the presence of a small pelvis depends on good obstetric judgment and technic. No matter what the antepartum care, the ultimate maternal and fetal mortality is determined by the conditions existing at labor.

CARDIAC DISEASE

Aside from all the dangers that may beset the normal woman in gestation and labor, the extra burden placed on the damaged heart makes the outlook for the cardiac patient always a doubtful one. This is particularly true when there have been previous episodes of decompensation or in the presence of auricular fibrillation, aortic stenosis with regurgitation, or class 2b or 3 mitral stenosis. Even with apparently good functional capacity in the earlier months of gestation, cardiac patients have been known to develop suddenly severe signs of heart failure. This happened in two of our cases, one of the patients dying at home a few weeks post partum.

Two per cent of our antepartum patients had organic heart disease. All were referred to the cardiac clinic for classification and from then on remained under the constant supervision of both clinics. More than half of these patients had adequate antepartum care. The

social service played an important part among our cardiac patients by easing their household duties and by encouraging regular attendance at the clinic. Several patients were hospitalized on the slightest signs of congestive heart failure. One very strict rule observed in the clinic is that all class 2a cardiac patients must be hospitalized for one month prior to the expected date of delivery. The class 2b and 3 cardiac patients are immediately hospitalized. For the type of patient we treat, this additional rest has undoubtedly contributed to bringing our cardiac patients to labor in a more favorable state of body and mind.

Although we had no immediate mortality, Lamb⁷ has shown that in a large series of cases the mortality of cardiac patients having antepartum care was 2.2 per cent, whereas in those who did not have such care the mortality rose to 20 per cent. This is understandable

born of syphilitic mothers present evidences of infection in the first year.

Antepartum treatment of syphilitic mothers undoubtedly reduces the percentage of fetal deaths, premature labors and syphilitic infants in a striking manner. The good results are roughly proportional to the amount of treatment given and the time at which it is started, even a few treatments in the last weeks of pregnancy will materially alter the outcome.⁹

DIABETES MELLITUS

Among the remaining defects found in the antepartum clinic, diabetes mellitus deserves particular attention. Our results in two mild cases of this disease do not reflect the important influence proper medical supervision plays on the final outcome. In the experience of Ronsheim,¹⁰ 50 per cent of pregnancies

* 2.6 per thousand living births

It is reasonable to expect and warrants early registration of pregnant women with heart disease. So far as lowering the maternal mortality is concerned, it would be even better if these patients consulted their physician before conception. Prevention of conception in cardiac patients is more commensurate with continued good health than interruption of pregnancy.

SYPHILIS

The routine use of the blood Wassermann and Kahn tests brought to light fourteen cases of syphilis. Six patients registered too late to receive adequate antepartum care. All the patients, however, were placed on bismuth and arsenic therapy as soon as the diagnosis was established, no matter what the period of gestation. All patients carried to full term. There were no stillbirths and none of the babies exhibited stigmas of congenital syphilis. This does not preclude the future development of syphilitic lesions in these children, as Parmelee and Halpern⁸ have found that not all children

in diabetic women end in abortion, miscarriage or premature labor. In thirty-six cases in which there were 121 pregnancies he reports only seventy-four live births. When the gestation has gone to term, the babies are larger than usual, presumably because of the hyperglycemia. This increases the cephalopelvic disproportion and adds to the hazards of labor.

Before the use of insulin the maternal and fetal mortalities were quite high. With insulin therapy the maternal death rate has been appreciably reduced but fetal mortality still continues at a high level. When one considers the outlook for the average diabetic patient in pregnancy it is most fortunate that this disease conduces toward sterility and makes its initial appearance in the fifth and sixth decades of life, a period in which there is naturally a lessened fecundity.

The parturition of clinic patients receiving adequate antepartum care (group C) was compared to that of unregistered patients admitted to the delivery room in active labor together with those registered patients

whose antepartum care was considered inadequate (group D). Groups C and D comprise all the patients delivered at Morrisania City Hospital during the year under study. These results are summarized in table 2.

On superficial examination it would seem that those with inadequate or no antepartum care fared better. There were more normal spontaneous deliveries, less maternal mortality, the same fetal mortality, and the

same morbidity. A more careful analysis will show that the lower operative incidence of 6 per cent in group D was due to the greater number of multiparas that the maternal deaths were in no way related to antepartum care (table 3).

Tyler, Watkins and Walker,¹¹ studying this problem (evaluation of antepartum care), balanced the adequate and inadequate antepartum care groups with reference to age, parity, color, race and economic status and were also unable to demonstrate statistically any benefits of antepartum care. Dr Tyler's¹² explanation of this unexpected observation was that "there are many things of value along educational lines which cannot be measured statistically, and the only danger in our conclusions apparently is that other people may get the idea that prenatal care is really of little proven value."

The main beneficiary of good antepartum care is the offspring. That explains in a large way why the trend of fetal mortality has been steadily downward since 1915, whereas the maternal mortality in the United States registration area has remained stationary.

The average maternal mortality rate in the United States, after excluding deaths due to abortions and ectopic gestations, is about 6 per thousand living births. That of Morrisania City Hospital from its inception in 1929 to 1934 inclusive is 5.3 (uncorrected). The causes of death are enumerated in table 4.

In theory, at least six of the fifteen deaths due to toxemia of pregnancy and two of the three deaths resulting from cardiac disease might not have occurred if more adequate antepartum care had been given. On the other hand, examination of table 4 also shows that in spite of adequate antepartum care six patients with toxemia of pregnancy and one with cardiac disease died. Have we the right therefore to claim that every

maternal death due to toxemia or cardiac disease is preventable if the patient had received proper antepartum supervision? Apparently not.

Deaths arising from hemorrhage and puerperal infections play a still greater role in the causation of maternal mortality. These deaths depend on the conduct of the delivery, however, and not on any negligence in antepartum observation.

Antepartum care has been stressed again and again as a major factor in the reduction of maternal mortality, yet our analysis definitely indicates that, outside of toxemia, there is little to recommend such emphasis. These claims distract attention from that phase of obstetric care where the blame should be placed, namely, the delivery itself. If any perceptible improvement in maternal mortality is to be accomplished, it can best result from the practice of sane obstetrics.

The most we should expect of antepartum care, so far as the mother is concerned, is that it will bring the woman to labor in a physical condition better able to withstand any necessary strain.

One other point is worth stressing here. The aroused public interest in maternal welfare has brought about an increased activity of quasimedical organizations in this problem. Social service workers and nurses are taking blood pressures, performing urinalyses and instructing obstetric patients in antepartum matters. It was recently suggested that antepartum care could very well be handled by a nurse after the initial examination by a competent physician, without in any way affecting the maternal and fetal outcome.¹¹ The advocates of this plan reach this conclusion because they are evaluating antepartum care in terms of maternal mortality. This is an unfortunate state of affairs because, if this belief becomes generally accepted, the true value of antepartum care will be lost to the public. Only 20 per cent of the defects found in the antepartum

clinic may be determined by the blood pressure and urine examinations. It is hardly conceivable that the other 80 per cent of antepartum defects can be ascertained by a nurse without first having had a thorough medical training. In the field of preventive medicine the cooperation of lay and semimedical organizations is desirable, but their activities should be strictly limited to education of the public and the relief of economic distress. Diagnosis and therapeutics must always remain the function of the physician.

COMPOUND SOLUTION OF TANNIC ACID

BERNARD FANTUS, MD

AND

H A DYNIEWICZ, PHC

CHICAGO

E C Davidson's¹ discovery of the life-saving qualities of the tannic acid crust therapy in the treatment of extensive burns has inaugurated a new era in the prognosis and treatment of such cases. Prior to that day, burns involving more than one third of the body surface were invariably fatal. Now, thanks to

Fig 1—Precipitation of blood with varying percentages of tannic acid after thirty minutes' standing. The denser the precipitate the shorter the column.

Before being in a position to form a judgment on either of these questions, one must have a clear mental picture of the reason for the results secured by the crusting of burns.

To explain the nothing less than marvelous life-saving qualities of the tannic acid treatment of extensive burns, recourse must be had to the concept of "white bleeding," i. e., the loss of an excessive amount of serum from the circulating blood in the inflammatory edema and exudate, as suggested by Underhill² and by Blalock,³ who found that plasma may be lost after a burn to the extent of 60 per cent of that normally occurring in the body. In man, the amount of blood has been estimated as equal to 7 per cent of the body weight. Thus, a person weighing 50 Kg has 3.5 Kg or as many liters of blood in his body. A loss of more than half the quantity of blood is likely to be fatal. A loss of 2 liters is certainly fatal. If a person loses several liters of serous exudate from his body, as he may with an extensive burn, the result, as far as the production of collapse is concerned, would be very similar to that of a hemorrhage and sufficient to account for death in many cases. This loss of plasma results in marked blood concentration, even up to 9 million or above (Locke,⁴ McClure and Allen⁵ and Harkins⁶).

The alternate theory that the crust renders insoluble and unabsorbable the hypothetical "burn toxins" has

this treatment, lives are saved even when burns extend over more than one half of the body surface.

This outstanding success has led to two results, the one being an indiscriminate use of tannic acid in burns of all kinds and sizes, and the other to attempts at improvement of the original Davidson technic.

been combated by experiments of Robert Kapsinow,⁷ who showed that a burned area is incapable of absorption of even so highly toxic a substance as strychnine. More recently, however, Mason, Paxton and Shoemaker⁸ have shown that potassium iodide is absorbed as easily from burned as from normal tissues. Harkins, Wilson and Stewart⁹ have found a depressor substance in extract of burned skin. Rosenthal¹⁰ has shown that in the blood of animals that have sustained a burn there circulates a body that lowers blood pressure and produces contraction of the guinea-pig uterus, acting therefore like histamine, but which is not histamine and for which the term "histaminoid" is proposed. It is probable that, should absorption of such substance occur from the damaged tissue, it is lessened to a considerable degree by the coagulation of the burned tissue, and the unyielding crust must also lessen the absorption by mechanically diminishing the hyperemia.

Whichever theory is correct—and both may be—the importance of a tightly adherent, rather rigid crust has been demonstrated most especially by Davidson's observation that, when he applied on the second or third day moist dressings to a patient with an extensive burn who seemed to be doing well, the symptoms of collapse returned as soon as the crust had become thoroughly softened.

It is obvious, therefore, that the production of a crust, and a good firm crust, must be the aim of this treatment. Such a crust cannot be secured without sacrificing some possibly viable tissue. This objection to the use of the tannic acid treatment in burns of limited extent, so well brought out by Taylor,¹¹ is certainly of sufficient importance to condemn this treatment for burns that do not endanger life. For such, other more "physiologic" dressings are available. But, with a burn of so great an extent as to endanger life, the sacrifice of the life of some of the surface cells must be taken into the bargain to save the life of the patient.

The various suggestions for improvement of the tannic acid solution may possibly best be discussed seriatim under such headings as strength of solution, the vehicle, hydrogen ion concentration, preservation of solution and antiseptic action.

Fig 2—Amount of dense gelatin tannate precipitate produced by tannic acid solution of varying strengths.

the rapid change a tannic acid solution undergoes on standing, this solution has to be prepared extemporaneously. Of late, spraying a 5 per cent solution of tannic acid at short intervals, until a good crust is obtained, has been found more practical. It is only when the front as well as the back of the body is involved that

the solution is employed in form of a compress applied to the back Pusitz¹² advises the use of a 10 per cent solution of tannic acid, and even a 20 per cent solution has been recommended, to obtain a more prompt crust formation (British Mine Department¹³)

A 25 per cent and even a 5 per cent solution of tannic acid has no germicidal effect and it might even be a means of infecting the surface with pathogenic bacteria. It has, on the other hand, been shown by Martin¹⁴ that 10 and 20 per cent tannic acid solutions completely destroy *B. coli*, *B. pyocyaneus*, *B. typhosus*, *Staphylococcus albus*, *Staphylococcus citreus* and *Streptococcus viridans* within twenty-four hours. Such solution also keeps somewhat better than a dilute solution, although it too will develop fungus growth in days or weeks, according to the method of keeping.

That the more concentrated solution produces a denser and therefore probably more efficient crust is shown by the following experiment

Fig 3—Precipitation of blood by 10 per cent tannic acid solution in water, in physiologic solution of sodium chloride and in Ringer's solution. Tannic acid in Ringer's solution produces the densest precipitate

EXPERIMENT 2—The same thing may also be shown by the curve of figure 2, which records the amount of dense gelatin tannate precipitate formed when 2 cc of tannic acid in various strengths (from 1 to 20 per cent) is added to 10 cc of 2 per cent solution of gelatin and the mixture is centrifugated for four hours

TABLE 1—Solutions Used in Experiment 1

Tannic Acid Solution	Height of Precipitate in Mm After Thirty Minutes Standing
1 per cent	40 mm
2 per cent	34 mm
4 per cent	23 mm
6 per cent	15 mm
8 per cent	13 mm
10 per cent	11 mm
20 per cent	8 mm

Figure 2 shows that complete dense precipitate of the gelatin does not occur until the 10 per cent solution is reached. In the lower strengths the supernatant fluid remains turbid, in spite of centrifugating, owing to the colloidal nature of the precipitate. Such flocculent precipitate would probably be worthless as far as crust formation is concerned.

It is concluded that 10 per cent of tannic acid is likely to be the most desirable strength of the solution.

THE VEHICLE

In view of the fact that the solution is intended to be applied to a raw surface, it seems logical that isotonicity might be desirable or, better, that the ions naturally existing in the tissue juices be present in the solution ("iso-tonia"). This suggests the use of physi-

ologic solution of sodium chloride or, still better, of Ringer's solution as the solvent.

EXPERIMENT 3—We added to 0.5 cc each of a 10 per cent suspension of defibrinated dog's blood in various test tubes 5 cc of the following solutions:

- 1 Ten per cent tannic acid in distilled water
- 2 Ten per cent tannic acid in physiologic solution of sodium chloride

Fig 4—Precipitation of blood by 10 per cent tannic acid solution at different degrees of pH. The densest precipitate at the lowest pH concentration occurs at pH 2.22

- 3 Ten per cent tannic acid in Ringer's solution

The height of the column after fifteen minutes' standing shows that the tannic acid in physiologic solution of sodium chloride produces a denser precipitate than the tannic acid in pure water and that the precipitate in Ringer's solution is still denser (fig 3).

We therefore believe that Ringer's solution is the best solvent for the tannic acid.

HYDROGEN ION CONCENTRATION

The suggestion has been advanced by Seeger¹⁶ that the tannic acid solution should be adjusted to a pH of 7.4 by the addition of sodium carbonate so as to minimize the irritation and edema produced by the more acid solution. He quotes a leather chemist "Were these acids used to tan skins, in the tanning of leather, these would be ruined." Seeger believes that these disadvantages are overcome by neutralizing the solution to the same pH as the blood, namely 7.4, and he cites two cases in which he believes superior results have been secured by the use of the neutral solution. He also states that the membrane was more pliable than that produced by the solutions of low pH.

Fig 5—Keeping qualities of 10 per cent tannic acid solution as demonstrated by means of quinine tannate precipitation. After two weeks rapid deterioration occurs.

Seeger's suggestion does not seem to have found favor in practice, and it can be demonstrated in the test tube (experiment 4, fig 4) that the precipitate resulting from the neutralized solution is much more colloidal and softer than that produced by tannic acid solution in water.

EXPERIMENT 4—To 5 cc of a 10 per cent solution of tannic acid in water, adjusted to varying degrees of hydrogen ion concentration, we add 0.5 cc of a 10 per cent suspension of defibrinated dog's blood. In one test tube we prepare a mixture

of the same proportions of dog's blood and tannic acid solution previously neutralized to pH 7.4 as recommended by Seeger. After agitation and permitting the precipitate to settle, it is found that the tannic acid precipitate in water (pH 3.22) is much denser and settles out of the solution very much more completely than does that from Seeger's solution. The latter forms a rather loose and bulky precipitate, some of which is so slow in settling to the bottom of the test tube that it requires many hours. It takes but fifteen to twenty minutes for the denser precipitate to settle.

It is obvious from experiment 4, results of which are shown in figure 4, that the density of the precipitate is influenced by

TABLE 2—Results of Culture Test of 10 per Cent Tannic Acid Solution in Antiseptics Dissolved in Ringer's Solution

Salicylic acid 1:500 (saturated solution)	++
Salicylic acid 1:1,000 1936	++
Salicylic acid 1:1,000 1934	++
Benzoic acid 1:500 (saturated solution)	+
Benzoic acid 1:1,000 1936	0
Benzoic acid 1:1,000 1934	0
Penzylparahydroxybenzoate (saturated solution)	+
Methylparahydroxybenzoate (saturated solution)	0
Chlorthymol (saturated solution)	0
Chrysoidin Y (saturated solution)	0

the hydrogen ion concentration of the solution. It will be seen from this graph that the densest complete precipitation occurs in the zone between pH 2.83 and 3.22. In the tubes of pH below 2.83 and above 6.42, not all of the tannic acid is precipitated, there being a turbid supernatant liquid, and, in the most acid and most alkaline tubes, there is a turbidity but no precipitation whatever.

It is concluded that, if density of precipitate is the criterion, the 10 per cent solution of tannic acid at its own pH of 3.22 will probably answer the purpose best.

PRESERVATION

While a 10 per cent solution of tannic acid has better keeping qualities than a more dilute solution, figure 5 shows, by means of quinine tannate precipitation, that after two weeks tannic acid deteriorates rapidly, so that it no longer removes quinine quantitatively from the solution.

Woodard and Cowland have shown that the hydrolysis of tannic acid into gallic acid and dextrose occurs extremely slowly in the absence of molds or of their enzymes. They also report that the addition of 1 part of cresol to 250¹⁷ or of 1 part thymol to 2,000 parts¹⁸ prevents this hydrolysis. They found acriflavine not successful in preservation. Experiments performed in our laboratory verify their result.

Fig. 6—Amount of gelatin tannate precipitate produced by 10 per cent tannic acid.

As the solution must be used in quantity and be applied to a very extensive raw surface, it is obvious that the least toxic efficient preservative is the best. Owing to the toxicity of mercury bichloride (1:2,000) and the volatility of cresol and thymol, which may force absorption of these bodies even under the possibly unfavorable conditions for absorption prevailing in the burn crust, we experimented chiefly with benzoic acid and salicylic acid and found that 1:1,000 benzoic acid or 1:1,000 salicylic acid preserved a 10 per cent solution of tannic acid for

a period of two and one-half years and that the solution at the end of this time is still capable of producing a satisfactory precipitate. By employing the "gelatin method" of experiment 2, it may be estimated that these solutions still contain 85 per cent of tannic acid (as shown in figure 6) after having been kept at room temperature for two and one-half years.

An objection to the use of salicylic acid might be raised on the strength of the observations of Hermann,¹⁹ who, on the basis of extensive experiments on bits of human skin obtained from cadavers, arrived at the conclusion that the addition of 0.1 per cent of salicylic acid markedly diminished the astringency of a 1 per cent solution of tannic acid because of the tendency of salicylic acid to cause swelling of tissue, which is much greater than that of water. We find that this is true of the quantity relations of the salicylic acid to tannic acid reported by Hermann. A 1 per cent tannic acid solution with 0.1 per cent of salicylic acid gives a bulkier and more flocculent and lighter precipitate than occurs when salicylic acid is absent. It is decidedly not true, however, with a 10 per cent tannic acid solution, as is shown by the results obtained with the technique of experiment 1 and presented in figure 7. The precipitate in the tubes up to 4 per cent is rather flocculent and not nearly as compact as seems desirable. Benzoic acid reacts exactly in the same manner as salicylic acid.

Fig. 7—Precipitation of blood by varying percentages of tannic acid solution containing 0.1 per cent salicylic acid after thirty minutes standing.

The conclusion is that benzoic acid as well as salicylic acid is successful as a preservative for the tannic acid solution.

ANTISEPTIC ACTION

In view of the general complaint that sepsis appears beneath the tannic acid crust in the course of several days, an attempt to make the crust bacteriostatic seems desirable so as to inhibit the growth of micro organisms either imprisoned beneath the crust or making their way under it by invasion from the loosening edges.

It therefore seemed worth while to see whether it would be possible to make the tannic acid crust bacteriostatic. Although mercury bichloride has been used for this purpose, it seems that, in view of the fact that the solution must be applied to very extensive raw surfaces, only nontoxic antiseptics are worth considering. We therefore selected the following agents for comparative study: salicylic acid, benzoic acid, methylparahydroxybenzoate, benzylparahydroxybenzoate, chlorthymol and chrysoidin Y. We dissolved 10 per cent tannic acid in a saturated solution of each of the six different agents, using Ringer's solution. A 10 per cent solution of tannic acid in Ringer's solution was used as a control.

Melted and cooled agar culture medium was inoculated with *Staphylococcus pyogenes-aureus* and then poured into a petri dish and permitted to solidify.

¹⁷ Woodard W. A. and Cowland A. N. cited in Tannic Acid Stable Solution. *Lancet* 2:767 (Sept. 30) 1933.

¹⁸ Woodard W. A. and Cowland A. N. The Stability of Aqueous Solutions of Gallotannic Acid. *Chemist & Druggist* July 29 1933 p. 142.

¹⁹ Hermann F. Ueber die Wirkung feuchter Umschlag. *Dtsch. Ztschr.* 50:277 (June) 1927.

Then 1 drop of the solution to be tested was dropped in the center of the culture plate and this was incubated for twenty-four hours. The results are reported as 0 when there was no halo of inhibition of growth and + or ++ according to the width of the area of inhibition of growth.

Bettman²⁰ has suggested applying immediately after the use of a 5 per cent solution of tannic acid a 10 per cent silver nitrate solution by means of cotton swabs. From twelve to twenty-four hours after the first treatment, any blebs that may have formed are treated as for the first application.

Having found salicylic acid 1:1,000 to be apparently quite as efficient as the 1:500 solution and that the latter tends to precipitate on standing, we next modified the experiment by superimposing a drop of 10 per cent silver nitrate on a drop of the salicylated tannic acid solution and we can show that the silver nitrate practically doubles the halo of inhibition produced by salicylic acid. This makes it appear that Bettman's suggestion is well taken and may be recommended as an improvement of the tannic acid treatment.

On the basis of these experiments we therefore recommend the formula given in table 3.

TABLE 3—Compound Solution of Tannic Acid

Potassium chloride	0.42 Gm
Calcium chloride	0.84 Gm
Salicylic acid	1.00 Gm
Sodium chloride	10.50 Gm
Tannic acid	100.00 Gm
Distilled water	to make 1,000 cc

Mix and permit to stand with occasional agitation until dissolved and filter if required to dispense a clear solution.

This solution is sufficiently stable to be kept on hand for use in the emergencies occasioned by extensive burns.

We also recommend that 10 per cent silver nitrate solution be applied to the tannic acid crust.

SUMMARY

A solution has been devised and its formula published that has advantages over the tannic acid solution in water for the following reasons:

1. It is endowed with good keeping qualities.
2. It produces a denser coagulum.
3. It has bacteriostatic action, which is absent in the plain tannic acid solution.

This solution is being used successfully for crust formation in the treatment of burns at the Cook County Hospital.

The Three Fundamental Subjects—If I were setting out to make a doctor of a young man entering a medical school where he could do what he chose, I would say spend your four years in three places—the anatomical dissecting room, the dead-house and the clinic. In these three places (provided the anatomist is not prohibited from a consideration of function) you will hear spoken of or see illustrated at some time or other in your course all that is vital in our present-day medical knowledge. These places represent the workshops of the three fundamental subjects from which all others have branched off, and yet they have come to be perhaps the most neglected in some of our greater schools where the confused and somewhat restive student is passed through a mill which, in great part, has no apparent relation to his ultimate goal—Cushing, Harvey, *Consecratio Medici* and Other Papers, Boston, Little, Brown & Co., 1928.

Clinical Notes, Suggestions and New Instruments

TREATMENT OF INVOLUTIONAL MELANCHOLIA BY ESTROGEN

J. EDWARD SUCKLE, M.D., COATESVILLE, PA.

The pathologic physiology of the menopause has been placed on a valid basis by the work of endocrinologists in the past ten years. Fluhmann¹ noted that following the menopause the anterior hypophysis hypertrophies and there is an increase in the amount of gonadotropic hormone of the anterior hypophysis in the blood serum of many of these women. The ovarian follicular hormone, estrogen, on the other hand, decreases.² Meyer, Leonard, Hisaw and Martin³ showed that the administration of estrogen diminished the gonad stimulating potency of the anterior hypophyses of castrate male and female rats.

In the treatment of involutional melancholia, estrogen has heretofore been used by different investigators with varying success. Recently⁴ the use of prolonged and adequate doses of estrogen raised the percentage of clinical cures. A similar method in the case reported here resulted in cure, although during the first month of treatment the case appeared refractory to treatment.

REPORT OF CASE

A woman, aged 47, seen March 10, 1936, had been in good physical and mental health until April 1934, when the menses became scantier. The usual irritability that occurred during the premenstrual interval increased, and she became very depressed and worried but could not specify any particular cause for this change in mental state. Mental depression became so profound later in April that she attempted suicide by inhalation of illuminating gas. Failing this, she made a second attempt at self annihilation in June and another in the autumn of the same year. In the intervals her insight was good, but the fear of not being relieved of her depression drove her to seek her own destruction. Six days before the patient was seen by me she left her home for a walk at 7 p. m. and did not return until 2 p. m. the afternoon of the following day. A check up on her activities revealed that she had walked 30 miles and had not eaten during that time. It was advised that the patient be removed to a mental hospital, but up to this time the husband was very anxious that the home be preserved and his wife remain with him. He became so distressed with the apparent hopelessness of the situation, however, that it was only after serious consideration that medical direction was altered.

On mental examination the patient appeared anxious and depressed. She summarized her state of mind as confusion, faulty memory and extreme irritability occurring from four to five days before and during menstruation. During the catamenia auditory hallucinations and delusions of philandering by her husband would manifest themselves. She was in good rapport, affect was lowered, and mental content was fairly good.

The menses began at 11 years and were regular every thirty days, the flow lasting from five to seven days. Her first pregnancy was normal, and resulted in a son now living and well. Her second pregnancy, full term, resulted in twins who died soon after birth. She had had no miscarriages.

Physical symptoms complained of included loss of weight (from 142 to 131 pounds [64 to 59 Kg.]), headaches associated with visual scotomas and occasional gastric upsets.

Previous medical history was essentially negative except for pneumonia and diphtheria, a reaction to vaccination, and the childhood exanthemas, chickenpox and measles.

The family history was interesting in that her mother is a chronic complainer, fussing about trivialities and bringing her petty troubles to her daughter. A ruction in family affairs

resulted in the patient's father and mother not speaking but residing in the same house

On physical examination the patient was well developed and well nourished. She was lying quietly in bed and did not appear to be acutely ill. There was no pallor of the mucous membranes and no enlargement of the thyroid. The ears and eyes were normal. There were many carious teeth. The lungs were clear. The heart was normal in size, sounds were good, not marred by murmurs. The pulse was regular, and radial arteries were not sclerotic. The abdomen was normal. Pelvic examination revealed a uterus of normal size in midposition; there was tenderness in the right fornix but the adnexa of both sides were not palpable. The cervix showed nabothian cysts and several well healed lacerations. The extremities were normal and neurologic examination was negative.

Since the patient was kept home during the entire time of active treatment routine laboratory examinations were omitted.

March 10, progynon (Schering), 45 rat units twice a day by mouth, was started.

March 18 the patient became excited and agitated. She felt an uncontrollable nervousness.

March 20, 5,000 rat units of estradiol benzoate (progynon-B) was given intramuscularly. Progynon by mouth was continued. Phenobarbital, three-fourths grain (0.05 Gm) twice daily, was given for allaying temporary motor excitement.

March 23, the patient was again restless and kept her husband awake until 5 a.m. While her husband was dozing in a chair downstairs, the patient stealthily crept up to him and punched him quite hard. She gave no reason for this.

March 29, 5,000 rat units of estradiol benzoate was given intramuscularly.

April 5, the patient reported for the first time that she was feeling better and that the periods of nervousness were decreasing. Estradiol benzoate, 5,000 rat units was given intramuscularly.

The daily oral dose of progynon-B was increased to 200 rat units twice daily.

April 12, 500 rat units of estradiol benzoate was given intramuscularly. This corresponded to the premenstrual interval, which was usually marked by increased irritability and nervousness, which for the first time were absent.

April 19, 500 rat units of estradiol benzoate was given intramuscularly. The patient was now assisting in duties about the house.

April 26, 500 rat units of estradiol benzoate was given intramuscularly. The condition continued to be good.

May 3, 500 rat units of estradiol benzoate was given intramuscularly.

May 10, 500 rat units of estradiol benzoate was given intramuscularly. The patient was now taking progynon tablets 200 rat units twice a day.

Mental improvement continued and the patient showed increased interest in her surroundings. She assisted in her household duties and enjoyed her favorite diversion embroidery. But during this time rest in the afternoon was insisted on and the patient had the constant supervision and companionship of an affable woman. Oral endocrine therapy was continued until June 11, when all essential medication was stopped.

The effect of this treatment on the menses is interesting. The April menses appeared three days late, were scanty and were of four days' duration. The May menses appeared twenty-four days late and lasted nine days, being quite profuse.

It has now been almost eight months since the patient began treatment and five months since treatment was stopped and she has remained in good mental and physical health.

COMMENT

The case here reported showed the importance of estrogen therapy over a long time. Two months after treatment was begun Werner and his co-workers reported that 761 per cent of their patients with involutional melancholia, treated with estrogen for six months, showed improvement. The case reported here likewise shows the improvement and favorable change made in the mental picture after intensive therapy.

SUMMARY

In a case of involutional melancholia treated with estrogen prolonged and adequate dosage was designated as the cause of cure.

THE CLOTTING TIME OF BLOOD FOLLOWING ADMINISTRATION OF HISTIDINE

LEON BLOCH M.D. JAMES KOSSE M.D.

AND
HEINRICH NECHIELES M.D. PH.D.
CHICAGO

Markedly increased coagulability of the blood of man and dog following ingestion of protein was reported in 1927 by Mills and one of us¹. Unaware of the literature on this subject, Burger and Schrade² repeated our work and confirmed it, they also found that histidine shortens blood clotting time considerably and believe that this may explain beneficial effects of histidine therapy which they observed in bleeding peptic ulcer.³

Our experience has been that small amounts of protein have very little effect on clotting time, and, since the dose of histidine employed by the German workers was only 5 cc. of a 4 per cent solution of laevo-histidine monohydrochloride (Larostidin), we did not feel that the reported effect of histidine on clotting time was due to a generic effect of amino acids but to a specific hitherto unknown property of that compound. Therefore the clotting time was measured in a group of three normal persons, in two persons with duodenal ulcer and in two dogs. Histidine (Larostidin) was administered by intramuscular and intravenous injection and by mouth. Before administration of histidine, controls of clotting time were done. In order to follow normal diurnal variations, clotting times were measured without histidine in the starving subject. Blood was obtained by venipuncture with a dry paraffined syringe. The first and the last 0.5 cc. of blood in the syringe were discarded. Only such samples were used in which the needle drew blood at the first puncture of the superficial vein. Two dry paraffined test tubes received 2 cc. of blood each. A stopwatch was used for timing. The tubes were tilted gently every half minute and the appearance of the first clotting (adherence to the wall of the tube) and the complete clotting were noted. Each experiment lasted from two and one-half to three hours.

1. Clotting time was measured in three normal subjects after 5 cc. of histidine by mouth. No change of clotting time was noted after histidine. The greatest variation was found in a control in which no histidine was given.

2. Clotting time was measured in two female patients with duodenal ulcer after intramuscular injection of histidine. In the first patient no change in clotting time was noted, in the second clotting time was prolonged.

3. Clotting time was measured in two normal dogs. The first dog (male, 20.5 Kg.) received 5 cc. of histidine intravenously. No significant change of clotting time was observed. The second dog (female, 18 Kg.) received 25 cc. of histidine by stomach tube. A reduction of clotting time from eleven minutes to six minutes was noted thirty minutes after ingestion, but in this dog clotting time varied between thirteen and one half and nine minutes without histidine (starving).

CONCLUSIONS

In none of the human subjects or dogs did histidine by mouth or by intramuscular injection produce a marked change in clotting time. In those experiments in which a change in clotting time occurred controls without histidine evidenced equal changes. It was thought that intravenous injection of histidine might produce a shortened clotting time, but the same variation occurred in the starving animal. Therefore histidine apparently has no effect on blood clotting time and its therapeutic use in bleeding peptic ulcers cannot be justified by its effect on clotting time.

CONTROL OF SYPHILIS

CLINICAL LECTURE AT ATLANTIC CITY SESSION

THOMAS PARRAN, MD

Surgeon General United States Public Health Service

WASHINGTON, D C

"I look upon the subject of syphilis as the great question of the day. It was formerly a question of treatment but that day has passed. It is now a question of prevention, of eradication, of the protection of the well against the contamination of the sick. In other words, it is no longer a question for the therapist but one for the sanitarian, the philanthropist, the legislator, the statesman. It is one of public health and as such we are bound to meet it. The time has come when we can no longer shut our eyes to its evil and we must deal with it precisely as we deal with other evils that affect the health of the people.

It is our duty to enlighten the public upon all questions of public health.

"Now what I propose in regard to syphilis is simply to give to the existing boards of health the same power over syphilis that they now possess over cholera, smallpox and yellow fever. They now have the power of ferreting out these diseases and they should have the same power of searching out the abode of syphilis and of sending its victims to hospitals for treatment. For stamping out the disease in towns and cities their boards of health must have plenary powers of absolute character over syphilis, not more so, however, than they now possess over smallpox.

"Thus I say that I would simply include syphilis in the great family of contagious or communicable diseases and make it subject to the same laws and regulations that we already possess for their management.

"Shall it be said that we, the representatives of the medical profession of a great nation, will longer let the people remain in ignorance of the dangers that surround them? No, my friends, we must boldly proclaim the truth and scatter it broadcast over the length and breadth of the land. We must call to our aid the press, the pulpit, yea, the women of the country. We must call upon our state and county medical societies to do our bidding and to cooperate with us. We must keep the subject not only before the profession but we must keep it before the people."

There must be many in this audience who think this is too unorthodox, too radical a doctrine, that these measures would violate the traditional patient-physician relationships. To them let me say that these are not my own words. They are quoted directly from the presidential address of Dr J Marion Sims¹ before this association in 1876, sixty-one years ago.

Forty-one years was to pass before the profession and our governmental agencies heeded the eloquent plea of Dr Sims. Then it was an abortive wartime effort, since we apparently thought that the spirochete was demobilized with the army. Now sixty years after Marion Sims we have joined again in a campaign against syphilis. The disease is still our leading public health problem. We know the cause of syphilis. We know how it spreads. We know how the individual can avoid the risk of infection. With the darkfield we

can diagnose the disease promptly as soon as it is infectious. In the serodiagnostic tests we have an accurate method of recognizing the disease in all except the first few weeks and in its later less active stages. Of great importance in preventing spread we have the arsphenamines, which will speedily sterilize open lesions. When used in conjunction with compounds of bismuth or mercury, most cases can be arrested or cured.

More important than these scientific weapons is another more recent one—an aroused public sentiment.

What is the problem of syphilis in the United States?

Each year more than 500,000 new cases occur in which medical care is sought.

When syphilis is looked for at least one hidden case is found for each one previously recognized.

According to best estimates, 60,000 children are born each year with congenital syphilis.

The disease causes from 10 to 12 per cent of all deaths from heart disease. Each case of cardiovascular syphilis on the average cuts twenty-two years from the expected life span. Of every hundred patients with syphilis in the Cooperative Clinical Group studies, ten had obvious signs of cardiovascular involvement. At autopsy more than one half of the syphilitic patients show cardiovascular lesions.

Although less accurate data are available on the amount of neurosyphilis, it is known that, among the untreated and poorly treated, 30 per cent show spinal fluid changes, 19 per cent some clinical symptoms, and that 10 per cent of admissions to state insane hospitals are the result of dementia paralytica.

We know the distribution of syphilis in the population—approximately one fifth of cases occur in persons under 20 years of age. Between the sexes there is a ratio of two males to one female infected. The disease is more prevalent in cities than in rural areas and is six times as prevalent among Negroes as among white persons. There is considerable geographic variation in prevalence, ranging from as low as 100 new cases per hundred thousand of the population each year seeking treatment in settled rural areas to 2,900 in some cities and, for the country as a whole, 390.

We know what treatment will accomplish. From the standpoint of spread, treatment is prevention. From the standpoint of the average individual the Clinical Cooperative Group observations, arrived at by critical professional and statistical analysis, tell us with almost slide-rule exactness what to expect from specific amounts and types of treatment in early and latent syphilis. Relapse, arrest, serologic response, cure, cardiovascular and central nervous system involvement, outcome of pregnancy, each is charted so that all may read the results of ten years of work by five of our leading clinics on a total of patients now approaching the 70,000 mark.

We know where syphilis is treated. One half of all practicing physicians are constantly treating one or more cases, representing 59 per cent of the total. The remainder are being cared for in the 1,343 clinics, dispensaries and public institutions of the country.

We know the specific obstacles to the prosecution of a successful campaign against syphilis. Medical and public opinion is agreed as to the actions needed to remove such obstacles.

One half of known cases are not recognized or do not seek medical care during the first year of the disease when the chance of spread and the opportunity of cure are greatest. Cases must be found and treated early. Every suspicious initial lesion should mean a darkfield

Read in the General Scientific Meetings at the Eighty Eighth Annual Session of the American Medical Association Atlantic City N J June 8 1937

¹ Address of J Marion Sims Tr A M A 1876 p 91

examination, repeated if necessary. The diagnosis of primary syphilis is a laboratory procedure. Physicians must look for syphilis in their general practice. Every pregnant woman must have a serodiagnostic test in as routine a manner as a urinalysis. Every hospital admission, every case of doubtful diagnosis, every physical examination, every life insurance examination should include a serodiagnostic test. Medical examinations before marriage should be required by law and should include laboratory evidence of freedom from syphilis. One in five men and three in five women coming for treatment were unaware of their disease until it was recognized in the course of some other examination. In population groups with a high prevalence, such as Negroes, Mexicans and Puerto Ricans, whole communities should have a blood test family by family. The Wassermann dragnet must be cast widely to find cases.

ATTITUDE OF THE GENERAL PRACTITIONER

The average doctor treating syphilis looks on the patient as an interesting case. He can do something about it, just as he gives his diabetic patients insulin, so he can begin his courses of arsphenamine and bismuth compounds. But he does not consider the patient with early syphilis as he would a patient with smallpox. "Where did you get the disease?" "Whom may you have exposed?" The case of smallpox is reported. In my opinion Marion Sims was right in urging similar control of syphilis. Every case of early syphilis must be looked on not simply as a patient but as a starting point in finding other infectious individuals.

The physician who undertakes the treatment of a case of syphilis assumes two general responsibilities. First, to the patient. He must see the patient through to a cure, regardless of the patient's financial condition, or he must refer the patient to a public clinic. Second, he must either inquire diligently concerning the source of the infection and contacts, get them under treatment, and inform the health officer that he has done so, or he must permit the health department itself to do this essential public health job. The patient who continues treatment faithfully need not have his privacy invaded as much as a scarlet fever patient, for example. The syphilis patient who stops treatment while still potentially infectious, however, violates all privileges of privacy.

Syphilis is an epidemic disease. Evidence is piling up that it does not spread through the population like a fog over the bottoms. Syphilis is kept alive and spreads in the population by a series of small epidemics. These can be traced as in any other epidemiologic work. Sources of infection and contact cases can be located and brought under treatment. As yet the health facilities to do this job have not been created in any except the occasional community. In fact, most communities have not yet defined their job. The unknown can rarely be attacked with success.

Even for those patients who start treatment, only one in four receives as much as twenty doses of an arsphenamine with a concomitant preparation of heavy metal. Too many doctors still are satisfied to give one or two courses and let the patient go if the blood serologic test becomes negative. A negative serologic test of the blood is no index of arrest or of cure or of later noninfectiousness. The two great barriers to cure, however, are the ignorance of the patient concerning the amount and kind of treatment which he needs, and the cost of treatment. Of the patients who do start treatment 75 per cent stop short of one year's

care. This is less than the minimum to insure against spread and later serious complications for the patient himself.

At least one half of the syphilitic patients of the country cannot afford to pay for treatment even at the minimum prevailing rates in private practice. This is especially true if the patient must bear the cost of blood and spinal fluid tests and of other special examinations. The same yardstick used in determining eligibility for public relief—food and shelter—is not adequate to measure the inability of a syphilitic patient to pay for treatment. Yet all over the land there are clinics which will admit only those patients who are already on the relief rolls. State laboratories in a dozen states will not examine a blood specimen unless the doctor sending it certifies that the patient is indigent. Whole communities, including cities of considerable size, have no public or eleemosynary provision for treating indigent cases of syphilis.

I do not advocate the treatment of all patients with syphilis at public expense. This should not be necessary or desirable. It will not be if practicing physicians will look for syphilis and know how to diagnose and treat it, both as a disease and as a communicable infection. Additional public and voluntary funds, however, are needed to remove the economic barrier to care for those unable to pay for such services. The National Conference on Venereal Disease Control stated that the public clinic is the backbone of any community program for the control of syphilis and recommended that public clinics should accept three types of patients:

- 1 Any patient for diagnosis and emergency treatment if infectious
- 2 Any patient referred by a private physician either for treatment or for an examination, consultation and return to private care
- 3 All other patients who are unable to pay private physicians

The natural concern of physicians lest public clinics intrude on private practice by treating patients able to pay, in my experience, has only a slight foundation. No patient who can pay a physician is willing to subject himself to the inconvenience of a crowded public clinic. This is true even of a good clinic. Very few of our clinics as yet are good clinics. More often they are treatment mills with scant individualized attention to patients. In one city recently my representative reported that "they give more attention to the examination of the dairy cattle supplying milk to the city than they do to the syphilitic patient in their clinic." Bad as is the average public clinic, the National Conference agreed that it gives as good care as the average private physician.

Not only is the laboratory service in many of our states restricted in amount, but recent check tests show that many public and private laboratories alike are rendering an inefficient service. Some of them are labeling as syphilitic one person in ten who does not have the disease. Others use such an insensitive technique that they miss one half of those who are syphilitic. The whole laboratory service of the country needs a complete overhauling. Every laboratory presuming to make serologic tests should be willing to meet minimum state standards of performance.

The picture is not all black, however. Much progress has been made during the past year through the stimulus of Social Security funds in providing in many states some of the elements of a successful control program. Of more importance, we are witnessing for the first

time a cooperative effort between the whole medical profession and the health agencies, federal, state and local, in a joint attack on this public health problem. At the last annual conference of presidents and secretaries of state medical societies it was unanimously voted that each state society be asked to appoint a special committee to cooperate with the state health department in syphilis control. More than half of the state societies have appointed such committees and are working out programs.

PLAN FOR CONTROL OF SYPHILIS

In a country as diverse as this, no one stock plan of syphilis control is applicable. In each state and in each city the problem needs to be studied and a plan of action developed to meet particular local needs. Certain basic principles, however, have general application. These principles may be summarized briefly as follows:

- 1 There should be a trained public health staff to deal with syphilis in each state and city.
 - 2 Minimum state laws should require reporting of cases, follow up of delinquents, and the finding of sources of infection and contacts.
 - 3 Premarital medical certificates, including sero-diagnostic tests, should be a legal requirement.
 - 4 Diagnostic services should be freely available to every physician without charge and should meet minimum state standards of performance.
 - 5 Treatment facilities should be of good quality, with convenient hours and location. Wherever possible the clinic service should be a part of an existing hospital dispensary. Hospital beds should be provided for patients needing bed care.
 - 6 The states should distribute antisypilitic drugs to physicians for the treatment of all patients.
 - 7 Routine serodiagnostic tests need to be used much more widely. In particular, every pregnancy, every hospital admission, every complete physical examination should include this test.
 - 8 The informative program in modern diagnosis, treatment and control should be prosecuted vigorously among physicians and health officers, especially through the use of trained consultants.
 - 9 The public educational program must be persistent, intensive, and aimed especially at those individuals in the age groups in which syphilis is most frequently acquired.
- If these principles are applied to meet varying local conditions, no one can doubt that the shadow of syphilis will be lifted from the land.

CONCLUSION

Sixty-one years ago Marion Sims pointed the way. With the passage of the years his opinion has been shared by some of the most eminent clinicians of the day, among them Sir William Osler. Speaking before the Medical Society of London, Osler's oration² "The Campaign Against Syphilis" did much to allay medical opposition to the then pending venereal disease control law. In it he said "We are committed, then, to a campaign of education and an elaborate scheme of treatment. Two circumstances make it probable that these measures—a good beginning let us grant—will not suffice in themselves to reach the enemy."

"Realizing as fully as any one the strong arguments against notification [of the venereal diseases], the gravity of the situation outweighs with me all private considerations."

² Osler, Sir William. *Lancet* 1 787 1917.

"To be successful in this fight we must have control of the patients. The treatment must be compulsory."

Among the closing words of his address were these: "That the state has at last intervened is ground for hope. In the matter of health you may trust the people. Once get democracy to realize that it is diseased and it displays a Job-like regard for its skin."

Within the past year the sentiment of organized medicine has been expressed in an editorial in *THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*³: "The conquest of syphilis is the next great objective in public health."

The history of medical progress shows instance after instance in which the combined forces of medicine and public health have conquered disease as far as public cooperation could be procured.

With the combined efforts of physicians, public health officials, educators and the public, syphilis can be conquered next.

The object of the Public Health Service in fighting syphilis is identical with the historic objective of the profession of which we are part. It is not to make industry more efficient, though we hope we shall. It is not to save Americans money, though success will save them very much. It is not to make any of us more comfortable and contented, though syphilis causes much discomfort and discontent. It is to make the lives of Americans more healthful and more secure.

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT
HOWARD A. CARTER, Secretary

HIGH TENSION (MODELS CP-990 AND HCP-990) ACCEPTABLE

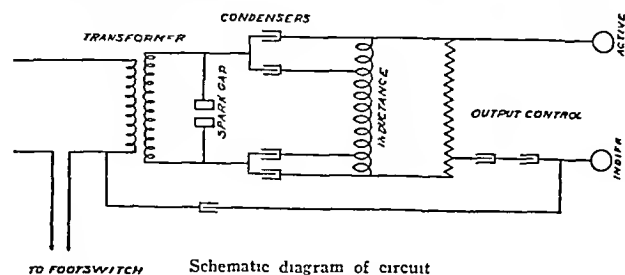

Manufacturer: High Tension Corporation, 118 West Twenty-Second Street, New York.

These electrosurgical units, designed for intermittent operation, are recommended for electrocoagulation, electrodeiccation and electrosurgery. The information made available to the Council indicates that when Model CP-990 is operated intermittently for one hour the resulting temperature rise of the transformer and the spark gap is within the limits of safety acceptable to the Council. The input power required does not exceed 230 watts.

This unit was used in a clinic acceptable to the Council and was found to be an effective instrument for the purpose for which it is intended. When Model CP-990 is built into a wooden cabinet it is known as Model HCP-990.

HCP 990 Electro Surgical Unit

TO FOOTSWITCH Schematic diagram of circuit

In view of the satisfactory performance of these units, the Council voted to include the High Tension Models CP 990 and HCP-990 in its list of accepted devices.

³ Control of Syphilis as the Next Public Health Objective, editorial, *J. A. M. A.* 106 1390 (April 18) 1936.

Council on Pharmacy and Chemistry

REPORTS OF THE COUNCIL

BECAUSE OF THE NUMEROUS INQUIRIES RECEIVED AND IN VIEW OF THE FACT THAT ELI LILLY AND COMPANY HAD NOT PRESENTED THE PRODUCT FOR THE COUNCIL'S CONSIDERATION THE COUNCIL DECIDED TO INVESTIGATE ENTORAL ON ITS OWN INITIATIVE. AN ASSOCIATE OF THE COUNCIL'S REFEREE COMPETENT IN THE FIELD OF BIOLOGIC PREPARATIONS WAS ASKED TO INVESTIGATE THE EVIDENCE FOR THIS MIXED BACTERIAL VACCINE WHICH IS BEING MARKETING AS AN AGENT FOR USE IN THE PREVENTION OF COLDS. AFTER CONSIDERING CAREFULLY THE REPORT OF THE REFEREE'S ASSOCIATE THE COUNCIL VOTED TO DECLARE ENTORAL UNACCEPTABLE FOR INCLUSION IN NEW AND NONOFFICIAL REMEDIES BECAUSE IT IS MARKETING WITH UNSUPPORTED UNWARRANTED THERAPEUTIC CLAIMS AND ADOPTED THE REPORT FOR PUBLICATION.

PAUL NICHOLAS LEECH Secretary

ENTORAL NOT ACCEPTABLE FOR N N R

I

"Entoral" is the name given by Eli Lilly and Company to a preparation of mixed bacterial vaccine for oral administration, recommended for the prevention of colds. According to the manufacturer's advertising, "Entoral" is put up in capsules, each containing pneumococci 25 billion, *H. influenzae* 5 billion, streptococci 15 billion, and *M. catarrhalis* 5 billion. The organisms are heat killed, are dried to a powder, and are said to contain a large amount of heterophile antigen.

"Entoral" is advocated as a prophylactic against colds in consequence of experiments made by Rockwell, Van Kirk and Powell¹. These authors believe that while colds are primarily due to a filtrable virus their severity is the result of secondary bacterial invasion. The scientific investigation which led them to the use of this method may be summarized as follows. Several observers have demonstrated that heterophile antigen occurs in various bacteria, and Powell² showed that rabbits would develop heterophile antibody if given feedings of heterophile antigen by mouth. (Heterophile antibody, often called "Forssman antibody," is a hemolysin for sheep red blood cells generated nonspecifically in rabbits by the injection of many animal tissues.) Bailey and Shorb³ produced heterophile antibody in rabbits by injection of several types of pneumococci and also reported that animals having a high titer of this antibody in the blood were resistant to pneumococcal infection, the serum, moreover, from such animals was able to confer passive immunity against pneumococcus. Although the number of these immunity experiments was small, they concluded that Forssman antibodies played a role in resistance to infection. Only a few animal experiments are reported. Recently Ross⁴ has shown that rats fed on pneumococci develop an active immunity against pneumococcal infection and also that their serum contains protective substances, this effect, however, is thought by Ross to be a specific one.

Believing, therefore, that an immunity to bacteria which are "sensitive" to heterophile antibody (i.e., presumably those which contain heterophile antigen) could be generated by feeding the antigen by mouth, Rockwell, Van Kirk and Powell¹ orally vaccinated 500 volunteers with an antigen containing in each dose 100 billion hemolytic streptococci and the same number of a type I pneumococcus, largely in the rough form. Volunteers took one dose each morning for the first week on an empty stomach and thereafter one dose a week for the remainder of the winter.

The results of the experiment on 500 volunteers with 536 controls were as follows. Thirty-eight patients who gave a history of continuous colds during the entire previous winter had only 108 colds per person during the treatment. Nine similarly severe cases in the control group had no comparable reduction. In the rest of the group of vaccinated individuals there was a reduction of 57 per cent in the number of colds as compared to the previous year, whereas in the control group a reduction of only 12 per cent took place. It was further shown, in a small group of individuals, that those developing a

very high titer of heterophile antibody were almost wholly immune to colds. This last observation has been recently expanded by Rockell and Van Kirk⁵. The clinical results are given in very brief tabular form.

In attempting to evaluate these results, one is struck by the fact that no mention is made as to the severity of infections occurring in the vaccinated group—that is, the duration of the colds and the frequency of complications. For this is the very feature that that one would expect to be chiefly affected according to the authors' own theory. All details of this kind are entirely omitted, and a simple record of the number of colds during the experimental period is given in tabular form and compared with the volunteers' average number for the preceding three years as obtained from the history. Further analysis of the authors' tables shows that this astonishing reduction in the number of colds occurred almost entirely in the group of nurses and medical students, whereas in the group of machine shop workers and life insurance company employees (presumably older and more stabilized in relation to their environment) the reduction was very much less significant.

It is also difficult to believe, either in the theory or from the evidence cited, that the presence of Forssman antibodies confers so great an immunity against infection, and it is on the presence of these antibodies that the authors' hypothesis rests. For instance, according to the work cited, the parenteral administration of ordinary "cold vaccines" should stimulate such antibody formation, and no parallel success has been obtained with their use in preventing colds.

CONCLUSION

After a consideration of the available evidence it would seem that the hypothesis on which "Entoral" is based is inadequately supported by experimental evidence and that the reports of its use contained in the literature are insufficiently documented. For these reasons the Council declared "Entoral" unacceptable for inclusion in New and Nonofficial Remedies.

II

Information was received in the Council's office that Entoral was apparently contaminated from a bacteriologic standpoint. A bacteriologist has therefore examined capsules of Entoral purchased both in the Midwest and in the East. His report included the following findings:

"While no live streptococci were found in either of the samples tested there were large numbers of viable spores of spore-forming aerobic bacilli. Most of the colonies in the plates were hemolytic and superficially resembled the colonies of hemolytic streptococci but they were all of sporulating aerobic bacilli. The counts indicated that there were from 13,000 to 15,000 of these living organisms in each capsule. It was noted that the capsules contain starch, evidently used as a filler, and it is possible that these bacterial spores were from that source. Just what the pathogenic significance of these organisms may be is doubtful. Ordinarily none of the aerobic spore-forming bacteria are considered markedly pathogenic, except the anthrax bacillus which was not found in this product. A few mice were injected intraperitoneally with broth suspensions of Entoral, representing up to about 1/10 of the contents of a single capsule. One mouse receiving 1/10 of one of the capsules in one lot died overnight and at autopsy the hemolytic sporulating bacilli were found in the heart blood. The other mice remained well. The conclusion reached by the bacteriologist is that Entoral is a heavily contaminated product from a bacteriologic standpoint."

A statement containing the foregoing information was transmitted to Eli Lilly and Company, and in reply the firm wrote (in part):

"Counts of 13,000 to 15,000 organisms per capsule are low and of no consequence. In general the organisms are contained in the starch, which is the same as any other starch used in pharmaceutical products. It is a regular food starch. The absurdity of attaching significance to the low bacterial count is recognized when one takes into consideration that the allowable bacterial count for milk in the State of Indiana is 100,000 per cc. For those who include milk in their daily diet, 500 cc per day is not an unusual amount, which would mean a total of 50 million organisms ingested with the milk alone. Compared to this,

1 Rockwell G E Van Kirk H C and Powell H M J Immunol 28 475 (June) 1935

2 Powell H M Am J Hyg 5 228 (March) 1925

3 Bailey G H and Shorb M S Am J Hyg 13 831 (May) 1931

4 Ross Victor J Immunol 27 235 (Sept.) 1934

5 Rockwell G E and Van Kirk H C J Immunol 31 417 (Nov.) 1936

the bacterial count of 'Entoral' is 0.03 per cent. As far as the bacteriologist's animal experiments are concerned it should be remembered that starch itself will cause a peritonitis and has been used for such purposes for many years. The animal test as run by the bacteriologist is not a valid test of the virulence of bacteria that may be associated in the starch. If the Council feels that it should make public the bacteriologist's report, then in all fairness they should make available to the same public the facts contained in this letter."

The Council held that the firm's reference to allowable bacterial counts of 100,000 per cc in milk in Indiana is quite beside the point. The Council believes that such milk should be regarded as heavily contaminated. Furthermore, if many of these bacteria in milk were spores, it would be interpreted as very dirty milk. Certified milk usually fails to show any spores in 10 cc samples. The Council does not mean to imply that the spore-forming organisms found in Entoral were pathogenic, and admits that the starch used in Entoral may be no more heavily contaminated than many other food starches. However, attention is called to the fact that food starch is usually cooked when used as food. It would appear that some other less highly contaminated material than food starch might better be used as a filler for pharmaceutical products of this character.

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT
PAUL NICHOLAS LEECH Secretary

LARODON 'ROCHE' NOT ACCEPTABLE FOR N N R

Larodon is the proprietary name under which Hoffmann-LaRoche, Inc., markets a product stated to be 1-phenyl-2,3-dimethyl-4-isopropyl-pyrazolon. The firm did not present the product for the Council's consideration but, prompted by the receipt of numerous inquiries, the Secretary of the Council asked the firm under date of Nov 5, 1935, to supply information concerning the composition of the product. The firm replied:

Your letter of November 5th inquiring about the structural formula of Larodon (Roche Preparation No 1947) has come to hand. This substance is 1-phenyl-2,3-dimethyl-4-isopropyl-pyrazolon and thus has the following structural formula:

"It is a finely crystalline white powder which has a slightly bitter taste. The melting point is 102-103°C. The substance dissolves readily in alcohol and ether sparingly so in water.

The new compound has been under investigation in European medical and dental clinics for several years (since 1932) and was found to exert a definite analgesic antipyretic action. On the strength of the clinical reports it was decided to introduce the remedy to the profession in this country. Before doing so we gave about a year prior to the first announcement trial supplies of Larodon to a number of important clinicians and dentists. Reports received from these also speak very favorably of the therapeutic action of the compound. It is expected that some clinical reports on Larodon will soon appear in the American literature and it is our intention to forward to the Council such clinical material with the usual technical information required in the presentation of a new remedy.

Larodon Roche is a one drug remedy and is distributed in tablets 5 grains each. For prescription writing the substance is available also in powder form in 1 ounce packages.

A series of promotional circulars representing Larodon as the acme of "progress in analgesia" has been issued by the firm, copies of which have been sent to the Council's office by physicians. One circular states:

Chemical pharmacological and clinical studies point unmistakably to the exceptional therapeutic performance of this newcomer to the non-official materia medica.

Another circular mentions as "Indications" for the use of Larodon the following:

Headache migraine neuralgia sciatica tabes dysmenorrhea arthritis lumbago myalgia head colds influenza grip tonsillitis pharyngitis laryngitis bronchitis pleurisy glandular fever rheumatic fever exanthemata especially measles and scarlet fever.

The product is advertised as being "kinder to the stomach" than acetylsalicylic acid. It is stated to be both analgesic and antipyretic, the claims are made that it "raises the pain-threshold without depressing the intellectual functions," that it "reduces febrile temperature, but does not affect normal temperature" and "never depresses temperature to sub-normal levels."

A consultant of the Council made a search of the literature and reported that he had been unable to find any article concerning the chemical or experimental examination of Larodon either during the past few months or prior to its introduction to the medical profession. The consultant stated, further, that because of the similarity of the formula of the drug, as given by Hoffmann-LaRoche, Inc., to that of aminopyrine and because of the known toxicity of the latter drug as well as the paucity of experimental and clinical proof of the worth of Larodon, one would hesitate to advise practicing physicians to use it.

Until adequate evidence for many of the claims advanced by the promoters of Larodon has been published, physicians may well ignore the firm's advice suggesting that Larodon be substituted for other well established analgesic and antipyretic drugs. If Hoffmann-LaRoche, Inc., has evidence to support the claims made, it should make this available to an impartial body such as the Council before launching such a vigorous campaign of advertising to the medical profession.

The Council declared Larodon 'Roche' unacceptable for New and Nonofficial Remedies because it is marketed with claims which are not supported by the available evidence.

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

PAUL NICHOLAS LEECH Secretary

COD LIVER OIL CONCENTRATE TABLETS-MERRELL—A cod liver oil concentrate in the form of tablets, each having a vitamin potency of not less than 3,150 units (U S P) of vitamin A and not less than 315 units (U S P) of vitamin D. Each gram of tablet has a vitamin potency of not less than 5,380 units (U S P) of vitamin A and not less than 538 units (U S P) of vitamin D.

Actions and Uses—Cod liver oil concentrate tablets-Merrell possess properties similar to those of cod liver oil so far as these depend on the fat soluble vitamin content of the latter.

Dosage—Two tablets daily or as prescribed by the physician.

Manufactured by Wm S Merrell Company Cincinnati. No U S patent or trademark.

The concentrate employed in the manufacture of cod liver oil concentrate tablets Merrell is obtained from cod liver oil by concentration of its unsaponifiable fraction. The vitamin A and D potencies of cod liver oil concentrate tablets Merrell are determined by the U S P method when assayed by this method the product is required to have a potency of not less than 3,150 vitamin A units per tablet or 5,380 vitamin A units per gram of tablet and 315 units of vitamin D per tablet or 538 vitamin D units per gram of tablet.

POLLEN EXTRACTS-MULFORD (See New and Nonofficial Remedies, 1936, p 41)

Also supplied in complete treatment packages consisting of one 2 cc vial containing 100 pollen units per cubic centimeter and one 10 cc vial containing 5,000 pollen units per cubic centimeter.

Prepared by the Mulford Biological Laboratories Sharp & Dohme Philadelphia and Baltimore.

DEXTROSE (See New and Nonofficial Remedies, 1936 p 286)

The following dosage forms have been accepted:

The Abbott Laboratories, North Chicago, Ill.

Ampoules Dextrose 50% 10 cc Each ampule contains 10 cc of a solution containing 6 Gm of dextrose U S P.

Ampoules Dextrose 50% 100 cc Each ampule contains 100 cc of a solution containing 60 Gm of dextrose U S P.

CARBARSONE (See New and Nonofficial Remedies, 1937, p 93)

The following dosage forms have been accepted:

Tablets Carbarsonone 0.05 Gm (3/4 grain)

Tablets Carbarsonone 0.25 Gm (3/4 grains)

Suppositories Carbarsonone 0.12 Gm (2 grains)

SATURDAY, JULY 17, 1937

TOTAL THYROIDECTOMY FOR CON- GESTIVE HEART FAILURE

Kocher and more recently Lahey have pointed out that a subtotal thyroidectomy performed on patients with congestive heart failure and hyperthyroidism frequently results in a definite and lasting improvement of the circulation. Blumgart found that in patients with congestive heart failure and a normal basal metabolic rate the basal velocity of the blood flow is greatly slowed and that, while the blood flow may be similarly slowed in patients with the low metabolic rate of myxedema, such patients do not show signs of congestive heart failure. He concluded that the diminished circulation of these patients is adequate for the diminished demands of the body. Observations on a patient who showed improvement following a subtotal thyroidectomy for suspected masked hyperthyroidism, later proved to be normal, suggested to Blumgart, Levine and Berlin¹ that the removal of the normal thyroid gland might be helpful in cardiac failure not due to thyrotoxicosis. Subtotal thyroidectomy performed on their first two patients caused a fall in the basal metabolic rate and clinical improvement as shown by the disappearance of edema, increased vital capacity of the lungs, and increased tolerance to exertion. During the next few weeks, however, the basal metabolic rate in these patients rose to the preoperative level and the clinical picture became less favorable. The authors therefore performed a total ablation of a normal thyroid on their third patient. This was followed by a striking and lasting improvement, which was attributed to a sustained lowering of the basal metabolic rate.

Another report eighteen months later, by Mixer, Blumgart and Berlin,² concerned fifty cases of congestive heart failure and twenty-five cases of intractable angina pectoris treated by total ablation of the normal thyroid. Complete relief was obtained in 35 per cent

of the anginal group, moderate improvement in 50 per cent, no improvement in 15 per cent, and no operative mortality. In the congestive heart failure group improvement took place in 55 per cent, moderate improvement in 26 per cent and no improvement in 7 per cent. The mortality rate was 12 per cent. Most of the failures in both groups were patients with low preoperative basal metabolic rates. These investigators therefore concluded that a low basal rate constitutes a contraindication to the operation. Cutler and Schmitker³ reported twenty-nine cases in which a total thyroidectomy was performed for the relief of severe anginal disease. Of twenty-one observed for periods varying from two to sixteen months, 46.7 per cent showed from 90 to 100 per cent improvement, 66.7 per cent from 75 to 100 per cent improvement, and 9.5 per cent less than 50 per cent improvement. They were impressed with the fact that the immediate relief from pain following thyroidectomy did not depend on the lowering of the basal metabolic rate, which as a rule is evident only some weeks later. Furthermore, patients with angina pectoris have no congestive heart failure and have a normal blood flow. Apparently the simple explanation of Blumgart did not seem to explain the improvement obtained by total ablation of the normal thyroid in angina pectoris.

Levine, Cutler and Eppinger⁴ suggest that the ablation of the thyroid may cause humoral alterations, particularly in the adrenal gland, in angina pectoris. In a later communication, Levine and Eppinger⁵ express the opinion that apart from the main effect of thyroidectomy in diminishing the work of the heart by decreasing the basal metabolic rate there is an additional important effect, one of diminution in the sensitivity of the heart to epinephrine. Thus Eppinger and Levine showed that, while epinephrine reproduced attacks of angina if injected before the operation, it failed to do so the second or third day after a total thyroidectomy.

Blumgart, on the other hand, maintains that the immediate relief of pain after thyroidectomy is due to interruption of the afferent nerve impulses from the heart at the time of operation and that the relief obtained by this mechanism is only temporary, lasting only a few weeks, and that permanent relief comes only with the lessened work of the heart and the development of surgical myxedema.

Parsons and Purks⁶ discuss data obtained from a survey of the literature and from an inquiry sent to all members of the American, Southern and Western surgical associations, the American Association for the Study of Goiter, and a number of American clinics.

² Mixer C. G., Blumgart H. L. and Berlin D. D. Total Ablation of Thyroid for Angina Pectoris and Congestive Heart Failure. *Ann Surg* 100: 570 (Oct.) 1934.

Information was obtained on 229 patients operated on for congestive heart failure and 133 patients operated on for the relief of angina pectoris. Data on complications were obtained in 291 cases. Tetany was noted in 10.3 per cent. It was, however, of a transient character in all but one case, in which it was the cause of death. Injury to the recurrent laryngeal nerve was recorded in 8.2 per cent of the cases. In no instance was it bilateral or permanent. From these figures it appears that serious complications are not sufficiently frequent to militate against the procedure. The operative mortality in the group with congestive heart failure was 10.48 per cent. Excellent results in this group were obtained in 34.63 per cent, moderate improvement in 28.78 per cent, slight improvement in 2.92 per cent and no improvement in 33.65 per cent. The operative mortality in the group of 133 cases of angina pectoris was 3.7 per cent. Excellent results were obtained in 55.46 per cent, moderate improvement in 28.12 per cent and no improvement in 12.5 per cent. They conclude that "there is slightly more than 50 per cent chance of satisfactory improvement in cases with congestive heart failure and somewhat better than 75 per cent satisfactory results in angina pectoris." They admit the inability to answer the question whether the operation prolongs life. "It is admittedly only a form of symptomatic treatment which in no way alters the underlying cardiac pathology. We must bear in mind that we are treating one disease by substitution of another even though the latter, myxedema, is milder and more amenable to treatment."

In the discussion of the paper by Parsons and Purks, Lahey⁷ stated that his experiences with twenty-seven cases carefully followed up were not gratifying. He did not believe that this operation would endure, because these patients have a limited cardiac reserve and myxedema is an undesirable state for a decompensated heart. He believes that the majority will return to decompensation later. He admits that better results were obtained in a few cases of angina pectoris, so that if a patient is willing to exchange an active state for the sluggish state of myxedema there were undoubtedly cases in which the anginal pain could be reduced. Lahey emphasized the fact that a total thyroidectomy is a difficult operation with a definite mortality and a high percentage of complications, and that it demands the highest degree of technical skill.

All commentators on this proposed treatment emphasize the point that improvement in the results will in the future depend on a careful selection of patients. The operation is definitely contraindicated in the presence of bacterial or rheumatic carditis, renal insufficiency, liver cirrhosis or the presence of a recent coronary occlusion. It is doubtful whether anything can be accomplished in the rapidly progressing cases that do not show any improvement on prolonged rest

in bed and medical therapy, and in cases in which the basal metabolic rate is low. Enough definite clinical improvement has been obtained in a sufficient number of cases of congestive heart failure, and even more in angina pectoris, to justify the operation of total thyroidectomy as a distinct advance in the treatment of certain types of cardiac disease.

DENTAL LESIONS AND SYSTEMIC DISEASE

A connection between oral and systemic disorders has been frequently noted. Acute and chronic poisoning by fluorine leaves indelible records on the teeth. The so-called blue line due to poisoning by lead, bismuth, mercury and other metals is well known. Vincent's infection associated with granulocytopenia is commonly observed. Subacute scurvy can sometimes be identified through a careful oral examination alone. Other examples may be easily added from general experience. Hence it is important to recognize the character and incidence of correlative symptoms if they are to be of diagnostic value.

It has been suggested but never adequately proved that tuberculous individuals are more susceptible to lesions of the soft and hard structures of the mouth than the healthy. An intensive investigation of the possible significant oral signs of tuberculosis has been reported from the Montefiore Hospital.¹

Fifteen hundred patients in all stages of tuberculosis were studied to determine whether dental and periodontal signs could be determined as pathognomonic of tuberculosis. No excess of dental or periodontal disease, however, was found in tuberculous persons. Neither were gingivitis and erosion found more frequently, even in the presence of extreme debilitation from far advanced pulmonary tuberculosis. An unusual increase in caries, erosion or alveolar destruction was not noted. There was no evidence of decalcification of teeth that could be ascribed to a demineralization initiated by tuberculosis. This accords with the similar observations of Wells, DeWitt and Long.² Secondary lesions, which occur late in the course of pulmonary tuberculosis in the form of ulcers on the tongue or buccal membranes, were uncommon. Vincent's infection did not occur more frequently in tuberculous patients than in others.

Miller,³ however, was able to observe caries and erosion resulting from the use of lozenges with a high sugar content. Inquiries revealed that these patients were using lozenges to relieve dryness of their mouths and throats, and to prevent excessive coughing. This may help to explain why caries and erosion have been believed to be associated with tuberculosis.

Current Comment

SIR SQUIRE SPRIGGE—AN EMINENT JOURNALIST

The death on June 17 of Sir Squire Sprigge, editor of the *Lancet* since 1909, marked the end of a great career in medical journalism. The history of the London *Lancet* and its founding have been previously recited in "The Life and Times of Thomas Wakley," written by him. It is interesting to learn that Sir Squire Sprigge received the cablegram which offered him a post on the *Lancet* when he was attending the Columbian Exposition in 1893. In 1909, at the age of 48, Squire Sprigge was promoted to the sole editorship. Since that time he had done much to advance medical education and to reform the curriculum in the interest of broad general knowledge. As editor of the *Lancet* he contributed largely to medical and general literature. Sir Squire Sprigge was the son of a physician, he had an innate feeling for medical problems and a tremendous influence, which he brought to bear on medical advancement. In the *Lancet* for June 26 appear a modern portrait and some fine discussions of his career which warrant the attention of all who are interested in medical history and in medical journalism. To the publishers of the *Lancet* THE JOURNAL extends sincere sympathy in the loss of a distinguished editor, a great author and a friend.

TROMBIDIOSIS, OR INFESTATION WITH CHIGGERS

Although Dorland's Medical Dictionary gives two definitions of the word "chigger," the second, "a harvest mite, or *Leptus* (*Trombicula*) *irritans*, of the southern United States," is more commonly adhered to. Parkhurst¹ has recently summarized a considerable amount of information on this subject. The chigger, which is the same approximately the world over, is the six-legged red larva of one branch of the family of Trombididae. Its essential characteristics are a hairy body with six legs terminating in claws, a rostrum bearing a pair of knifelike mandibles and two palpaе with five joints, provided with a trifold claw. Some species of this family have been reported from all the faunal areas of the tropical and temperate zones. In the northern hemisphere they may be encountered from the latter part of April until late in October. In the southern hemisphere they are found from November to March. *Trombicula irritans* Riley is the common North American chigger, according to Ewing. In the warm days of spring the adults, male and female, end their hibernation in the upper layers of the ground and emerge. From two to four weeks later about three or four hundred eggs are laid and after three or four weeks larvae hatch on the surface of the ground and on low plants. These larvae have six legs, are brick red and must apparently lead a parasitic existence in order to survive. Their hosts are reported to include

domestic animals, rodents, birds, certain reptiles and man. The larva does not change hosts and does not generally remain on the human body more than from two to four days. It drops off engorged with a fatty predigested tissue juice (not blood). The nymphs and adults are scavengers and do not infest man or animals. It has been shown that the chigger is the vector of the Japanese river fever or pseudotyphus and that the virus or organism enters the larva from the tissue of the host. According to Parkhurst there is some difference of opinion as to the location on the vegetation of chiggers. He feels, however, in common with some others, that many of the mites are actually present on tall weeds and bushes as well as on grasses. They may invade the skin of the host from the neck and shoulders down but are more commonly found from the feet and ankles up. As a rule they do not fasten themselves and feed immediately but run rapidly until they meet with an obstacle, such as a garter or a belt. Many attach themselves to the skin at points near which such obstacles are encountered. Unlike the itch mite, the chigger does not burrow but merely pierces the epidermis as deeply as possible with its pointed mandibular claws. When the chigger has thus anchored itself, it remains quietly in place and begins a process of epidermal liquefaction by extra-oral digestion. The phases of reaction have been studied and may be described as spastic ischemia, exudative arteriolitis and vasolysis with hemorrhage and vesiculation, followed by primary resorption and terminal repair. Thus, clinically, the earliest lesion to be noticed by the patient is seldom the actual bite but rather the earliest stage of the tissue reaction. The vesicle is often scratched and may be followed by a secondary infection. If it is not excoriated, it usually dries and is followed by scaling. Involution begins about the third day and is extremely slow. The diagnosis, according to Parkhurst, offers little difficulty as a rule. Immunity has been said to occur following repeated exposure, and some races are said to be relatively immune. Treatment consists of removing the mites, which is perhaps best accomplished by an application of benzene, kerosene or a copper compound, followed by bathing for a half hour with liberal application of soap, and a complete change of clothing. The second objective is relief of the severe itching by palliative measures, and the treatment or prevention of secondary infection. A variety of such measures has been tried. Parkhurst found that brief applications of rubbing alcohol (70 per cent) to the affected areas, followed immediately by a mild antiseptic antipruritic ointment, is satisfactory. A clean and generally effective application has been boric acid ointment U. S. P., to which may be added from 1 to 2 per cent of phenol and 0.2 per cent of menthol. Infestation may be fairly well prevented by the use of protective clothing or by dusting the skin with sulfur. By prolonged efforts, Parkhurst states, foci of chiggers in infested areas may be destroyed. This objective may be accomplished by removing weed and underbrush, keeping the grass cut short and carefully spraying the vegetation with sulfur by means of a dust gun or dust blower.

¹ Parkhurst, H. J. Trombidiosis (Infestation with Chiggers). Arch. Dermat. & Syph. 35: 1011 (June) 1937.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES NEW HOSPITALS EDUCATION AND PUBLIC HEALTH)

ARIZONA

Personal—Dr Roland A. Davison has been appointed to succeed Dr Louis C. B. Baldwin as medical director of the Desert Sanatorium, Tucson at the expiration of the latter's term next fall, it is reported. Dr Baldwin is returning to private practice.

ARKANSAS

District Meetings—At a meeting of the Eighth Council District Medical Society in Russellville, June 22, the following spoke: Dr Lycurgus Gardner, Russellville, "Diagnosis and Treatment of Simpler Eye Conditions", Mr Robert White, Russellville, "The Lawyer and Doctor", Dr George F. Jackson, Little Rock, "Cancer". A round table discussion was held on "Obstetric Experiences—Believe 'Em or Not". Among others, Dr Joseph F. Shuffield, Little Rock, addressed the Ninth Council District Medical Society, June 1, in Harrison, on "Common Fractures of the Lower Extremity" and Dr William B. Grayson, Little Rock, state health officer, "Social Security Act as Pertains to the State Health Department".

DISTRICT OF COLUMBIA

Personal—Dr Sara E. Branham, senior bacteriologist, U. S. Public Health Service, Washington, received the honorary degree of doctor of science from the University of Colorado at its commencement exercises, June 14, in recognition of her contributions to bacteriology in relation to public health. Dr Henry H. Hazen, professor of dermatology, Howard University College of Medicine, Washington, was elected president of the Washington Social Hygiene Society, June 12, filling the vacancy left by the late Dr William A. White.

IDAHO

Personal—Dr Charles R. Lowe, superintendent of the State Hospital South, Blackfoot, since 1930, has been appointed director of the Nampa State School and Colony to succeed Dr D. Orr Poynter, who resigned after several years in the position, ever since the school was built, it was reported.

ILLINOIS

University News—Alpha Epsilon Delta Honorary Pre-medical Fraternity announces the installation of the Illinois Alpha chapter at Illinois Wesleyan University, Bloomington, May 21. Emmett B. Carmichael, Ph.D., professor of physiologic chemistry at the University of Alabama School of Medicine, and grand president of the fraternity, conducted the installation ceremonies. This was the eighteenth chapter installed since the establishment of the fraternity at the University of Alabama in 1926.

Vital Statistics—The general death rate for Illinois was 118 per thousand of population in 1936 as compared with 109 in 1935, according to a recent report. Notifiable diseases decreased, the totals for 1936 and 1935 being 124,407 and 214,385. The fifth epidemic wave of poliomyelitis in twenty years occurred with 689 cases, 422 cases of smallpox were recorded, as compared with eighty-three in 1935 while greater prevalence was reported for pneumonia, syphilis, erysipelas, mumps and trachoma. For the last named there were 1,624 cases against 1,211 in 1935. Six cases of Rocky Mountain spotted fever were recorded during the year, twelve of pellagra, 165 of bacillary dysentery and one of leprosy. Fifty-six cases of tetanus and ninety-one of tularemia were reported, giving an incidence of about 60 per cent above that for 1935. Excessive heat caused 1,360 deaths in 1936 against ninety one in 1935 and heart disease accounted for 24,913 against 21,803 in 1935. The mortality was noticeably higher from cancer, diabetes, apoplexy and nephritis, said the report. The 5,245 deaths among infants gave a rate of 467 per thousand births slightly higher than for the year before, 454, and was attributed to an increase in deaths from diarrhea and enteritis. There were 476 deaths among women from puerperal causes giving a lower rate 42 per thousand births, than in any previous year. The number of births, 112,158 was somewhat higher than in 1935 but the rate was unchanged, 143. There were 19,348 more

births than deaths, the excess being the lowest on record. Motor vehicle accidents accounted for 2,464 deaths, 130 more than in 1935 but 111 less than in 1934, when the total of 2,575 established a new all time high.

INDIANA

Personal—Dr William E. Arbuckle has been appointed police and fire surgeon of Indianapolis to succeed Dr Frank T. Dowd. The latter was appointed a member of the Indiana State Board of Beauticians succeeding Dr Theodore D. Rhodes. Dr and Mrs John C. Sharrer, Francesville, observed their fifty-eighth wedding anniversary June 9.

Society News—The Marshall County Medical Society was addressed in Plymouth, June 23, by Dr Karl A. Meyer, Chicago, on "Recent Advances in Intestinal Surgery". At a meeting of the Gibson County Medical Society in Princeton, June 14, Dr Harold M. Trusler, Indianapolis, spoke on plastic surgery. Judge W. Lynn Parkinson, Lafayette, discussed care of crippled and diseased children and the Indiana penal system, June 15 at a meeting of the Tippecanoe County Medical Society in Lafayette. The Grant County Medical Society heard Dr Sidney Price, Marion, discuss "The Modern Management of Peptic Ulcer" June 24. At a meeting of the Park Vermillion County Medical Society, Clinton, June 16, Dr James C. Carter, Indianapolis, discussed summer diseases of children.

IOWA

Personal—Dr Daniel W. Coughlan has been appointed clinical supervisor at the Broadlawns Polk County Public Hospitals, Des Moines, effective July 1. Dr Lester J. Spinharney has been appointed health officer of Cherokee, succeeding the late Dr Charles F. Quinn. Dr Spinharney held the post from 1927 to 1931.

KENTUCKY

Personal—Dr Clifford N. Heisel, Covington, was the guest of honor at a dinner given by the staff of St. Elizabeth Hospital, June 16, in observance of the twenty-fifth anniversary of his connection with the hospital. Dr Chadwick W. Christine, Flemingsburg, has been appointed assistant health officer of Jefferson County.

Society News—Physicians of Caldwell, Crittenden and Lyon counties at a meeting in Princeton recently formed a tri-county medical society with Dr Thomas A. Henson, Frazer, Marion, as president and Dr William L. Cash, Princeton, as secretary. Drs Homer A. Gilliam and Jacob M. Mayer addressed the Graves County Medical Society, Mayfield, June 23, on "Injection of Hemorrhoids" and "Intestinal Obstruction," respectively. At the annual meeting of the Southwestern Kentucky Medical Association in May the speakers included:

Dr. Drew W. Luten St. Louis Management of Congestive Heart Failure
Dr. Frank Lee Stone Chicago Sterility
Dr. Clay O. Miller Chicago Structures of the Urethra and Associated Complications
Dr. Euclid M. Smith Hot Springs National Park Ark. Etiology and Pathology of Arthritis
Dr. John J. Shea Memphis Tenn. Sinusitis
Dr. Joseph A. Crisler Memphis Surgery—Notes from Clinical Trips

LOUISIANA

New Society for Mental Hygiene—The Louisiana Society for Mental Hygiene was organized in New Orleans, May 8, as an affiliate of the National Committee for Mental Hygiene. New Orleans. Officers include Drs Joseph A. O'Hara, New Orleans, president and executive officer, state health department, president, and Paul C. Young, Ph.D., professor of psychology, Louisiana State University, Baton Rouge, executive secretary.

MARYLAND

Personal—Abel Wolman, chief engineer of the state department of health, has been appointed professor of sanitary engineering at Johns Hopkins University.

Society News—Dr Simeon Burt Wolbach, Shattuck professor of pathologic anatomy, Harvard University Medical School, Boston, gave one of the De Lamar Lectures in hygiene, May 11, at the Johns Hopkins University School of Hygiene and Public Health, Baltimore. His subject was "Morphological Aspects of Vitamin Deficiencies."

Dr Abel's Eightieth Birthday—Dr John J. Abel, emeritus professor of pharmacology, Johns Hopkins University School of Medicine, Baltimore, celebrated his eightieth birthday, May 19, at a banquet given in the Welch Medical Library, attended by colleagues and former students. A scroll bearing the names and greetings of those in attendance was presented to

Dr Abel at the conclusion of the dinner. Dr Abel was born in Cleveland in May, 1857. He graduated in medicine at the University of Strassburg in 1888, and served as lecturer and professor of materia medica and therapeutics, University of Michigan School of Medicine, from 1891 to 1893, when he joined the faculty of Johns Hopkins as professor of pharmacology, holding the position until 1932, when he became professor emeritus. Since 1932 he has been director of the Laboratory for Endocrine Research. He was editor of the *Journal of Pharmacology and Experimental Therapeutics* from 1909 to 1932. He is a member of many scientific societies and has received the following awards: Research Corporation prize, 1925; Willard Gibbs medal, Chicago section of the American Chemical Society, 1926; gold medal of the Society of Apothecaries, London, 1928; Philip A. Conne medal, New York Chemists' Club, 1932, and the Kober medal, 1934. He delivered the first Kober Lecture sponsored by the Kober Foundation under the auspices of the Association of American Physicians in 1925.

MASSACHUSETTS

Veteran Physicians Honored—Fifteen physicians were presented with scrolls commemorating fifty years' membership in the Worcester District Medical Society at its annual meeting, May 12, in Worcester. They are Drs. Levi White, Samuel B. Woodward, Roscoe W. Swan, William C. Fogerty, William J. Delahanty, David Harrower, Charles A. Drew, John J. Brennan, Worcester; Walter P. Bowers, Clinton; Charles A. Deland, Warren; William H. Workman, Newton; George L. Tobey, Bremen, Maine; George A. Brown, Barre, and Albert C. Getchell and Homer Gage, Worcester. Dr. Charles A. Sparrow addressed the meeting on "Social Security and the Physician," and Dr. William A. Bryan was elected president of the society.

Dr. Gordon Appointed Professor of Preventive Medicine—Dr. John E. Gordon, field director of the International Health Division of the Rockefeller Foundation, New York, has been appointed professor of preventive medicine and epidemiology at Harvard University Medical School. According to the *New York Times*, the appointment is effective Sept. 1, 1938. Dr. Gordon was born in Austin, Minn., June 18, 1890, and received his degree in medicine from Rush Medical College, Chicago, in 1925. He served as instructor in bacteriology at the University of Chicago for two years and in 1925 became assistant medical superintendent at the Municipal Contagious Disease Hospital in Chicago. From 1927 to 1934 he was medical director of the communicable disease division of the Herman Kiefer Hospital, Detroit. In 1931 he was on the Michigan state commission on poliomyelitis and in the same year served on the committee of scientific exhibit on poliomyelitis for the annual session of the American Medical Association. In 1931 he was chairman of the Section on Preventive and Industrial Medicine and Public Health of the Association. For three years Dr. Gordon has been studying scarlet fever in Rumania for the Rockefeller Foundation.

MICHIGAN

University News—Dr. Charles W. Edmunds, professor of materia medica and therapeutics, University of Michigan Medical School, Ann Arbor, has been appointed to the executive board of the Horace H. Rackham School of Graduate Studies.

Personal—Dr. James H. Dempster, Detroit, editor of the *Journal of the Michigan State Medical Society*, has been appointed lecturer on medical writing at the Wayne University School of Medicine, Detroit. Dr. Edmund F. Collins has been appointed to succeed Dr. Warren L. Babcock as superintendent and director of Grace Hospital, effective October 1, it is reported. Dr. Babcock is retiring after thirty-four years in the position. Dr. Walter J. Wilson Sr., Detroit, has been made an honorary member of the Wayne County Medical Society. Dr. John L. Glees, Detroit, has retired from private practice to become medical director of the Briggs Manufacturing Company.

MINNESOTA

Personal—Dr. Wesley W. Spink, formerly of Duluth, has been appointed professor of medicine at the University of Minnesota School of Medicine, according to *Minnesota Medicine*. Dr. Edward J. Engberg, St. Paul, formerly secretary, Minnesota State Board of Medical Examiners, has been appointed superintendent of the Faribault School for the Feeble-minded, to succeed Dr. James M. Murdoch, resigned, effective July 1. Dr. Waltman Walters, Rochester, received the honorary degree of doctor of science from Dartmouth College, Hanover, N. H., at its recent commencement.

Chiropractor Given Suspended Sentence—Chester E. Paul, St. Paul, licensed chiropractor, pleaded guilty to an indictment charging him with performing an illegal operation, April 28, on a woman, aged 24, who died May 19. The indictment charged Paul with manslaughter in the first degree and with the crime of abortion in connection with this case, according to the state board of medical examiners. On the surrender in court of his basic science certificate and his license to practice chiropractic, Paul was sentenced to a term of not to exceed four years in a state penal institution and was placed on probation in custody of the probation officer of Ramsey County with the admonition not to practice healing in any way.

MISSOURI

University News—The Alumni Association of Washington University School of Medicine celebrated the fiftieth anniversary of the class of 1887 in the gold room of the Jefferson Hotel, St. Louis, June 5.

Society News—Dr. Howard A. Rusk, St. Louis, read a paper before a recent meeting of the St. Louis County Medical Society, entitled "Urticaria—A New Approach." Dr. Leon Bromberg, St. Louis, addressed the society, June 9, on "Artificial Fever Therapy." Dr. Edmund H. M. Lissack, Concordia, addressed the Lafayette County Medical Society at Lexington, May 25, on "Symptoms and Diagnosis of Pyelitis."

MONTANA

Personal—G. Albin Matson, Ph.D., associate professor of bacteriology, Montana State University, Missoula, has been appointed an assistant professor in the department of bacteriology and pathology, University of Utah School of Medicine.

NEVADA

Human Plague—A provisional laboratory diagnosis of plague has been made in a case of illness of a person who had been living in Lake Tahoe, Douglas County, about 6 miles from the cottage of a patient who developed the disease last year, according to *Public Health Reports*, June 25.

NEW HAMPSHIRE

Society News—Drs. Hiram Houston Merritt and Leo Alexander, Boston, conducted a clinicopathologic conference on neurologic conditions as guests of the Merrimack County and Center District Medical Society at its spring meeting in Concord. At the semiannual meeting of the Hillsborough County Medical Society at Nashua, May 4, Drs. Rodenck, Heffron, Boston, and William Joseph Paul Dye, Wolfeboro, spoke on "Pneumonia, Its Treatment with Serum and Its Prevention" and "Traumatic Injuries of the Hands with Particular Reference to a Method of Tendon Suture" respectively. Dr. John Rock, Boston, addressed the Grafton County Medical Society, Woodsville, at its spring meeting, on "Caution and Diagnosis of Sterility" and "A Consideration of the 'Safe Period'." Dr. Samuel T. Ladd, Portsmouth, spoke on "The Civic Responsibility of the Doctor in the Community."

NEW MEXICO

Hospital Dedicated—Holy Cross Hospital, recently given to the town of Taos by Mable Dodge Luhan, was dedicated May 3 by the Archbishop of Santa Fe. The hospital was opened in December 1936, the first the community has ever had.

NEW YORK

Personal—Dr. Ralph M. Vincent, Maine, has been appointed epidemiologist-in-training on the staff of the state department of health. Dr. David D. Rutstein, Boston, has been appointed full time medical consultant in pneumonia control on the staff of the state department of health. Dr. Edward R. Baldwin, Saranac Lake, received the honorary degree of doctor of laws at the annual commencement of Dartmouth College, Hanover, N. H.

Outbreak of Gastro-Enteritis—The water supply was believed to be the cause of an outbreak of 141 cases of gastro-enteritis in the village of Altamont, Albany County, in May. All persons who were ill reported that they had drunk the village water, while none of 125 interviewed who denied drinking from that supply had been attacked. Laboratory examination of samples of untreated water showed contamination.

Letchworth Village Superintendent Named—Dr. Harry C. Storrs, medical superintendent of the Wassauc State School, Wassauc, has been appointed superintendent of Letchworth.

Village, Thiells, to succeed the late Dr Charles S Little Dr Storrs, a graduate of Dartmouth Medical School, Hanover, N H, was first assistant physician at Letchworth Village for many years He is president of the American Association on Mental Deficiency

Society News—Drs Mather Cleveland and David M Bosworth, New York, addressed the Dutchess County Medical Society, Poughkeepsie, May 21, on "A Critical Analysis of Fifty Consecutive Cases of Fracture of the Neck of the Femur, Emphasizing Certain Causes of Nonunion"—Dr Madge C L McGinness, New York, was elected president of the New York State Women's Medical Society at its annual meeting in Rochester in May Drs Kathleen L Buck Rochester and Alice S Woolley, Poughkeepsie, were elected vice presidents and Dr Marguerite P McCarthy, Solvay, secretary—Dr Stuart B Blakely, Binghamton, addressed the Cortland County Medical Society, Cortland, recently, on "Diagnosis and Treatment of Human Sterility"

Obstetric Council in Erie County—The Medical Society of the County of Erie recently adopted a plan for an obstetric council following the final report of a special survey committee that made a study of maternal mortality The society requested each hospital taking obstetric cases to appoint a representative from its obstetric staff to the council The purposes of the council will be to carry on the statistical and educational work of the survey with the general goal of lowering the puerperal mortality rate and improving obstetric practice It will stand as a source of authoritative information on obstetrics to social agencies and the community at large, and will cooperate with recognized agencies in education of the public concerning accepted standards of obstetric care Dr Edward P Forrester is chairman and Dr Louis A Siegel secretary of the council Other members are Drs Francis C Goldsborough, Louis N La Mantia, Edward E Haley, Edward G Winkler, Curtis C Johnson, Harriet Hosmer, Abram L Weil, Bernard A Mohan and Milton G Potter

New York City

New X-Ray Unit—Contracts have been let for construction of a new x-ray plant at Long Island College Hospital, it was recently announced A high voltage therapy unit of 400,000 volts and modern equipment for diagnosis will be included in the new installation, which will cost about \$60,000 It is to be a memorial to the late Albert L Mason, for many years president of the hospital and a member of the board of regents Mrs Mason and the board have provided the funds

Dr Frank Honored—The June issue of the *American Journal of Obstetrics and Gynecology* was dedicated to the honor of Dr Robert Tilden Frank on the occasion of his retirement from active service as attending gynecologist at Mount Sinai Hospital The issue is made up of contributions from clinicians and research workers in various countries Dr Frank, who is 62 years old, was graduated from the College of Physicians and Surgeons of Columbia University in 1900 He was appointed to the staff of Mount Sinai in 1925

Grants to Columbia for Medical Research—Columbia University recently announced a grant of \$50,000 from the Josiah Macy Jr Foundation to further the program of graduate medical education made possible by the new laboratory facilities now under construction at the medical school (THE JOURNAL March 27, p 1127) Other gifts announced were

National Research Council \$13,500 for research under Dr Philip E Smith and the department of anatomy

Carnegie Corporation \$4,300 for research in biologic chemistry

Rockefeller Foundation \$1,800 to be applied on the salary of a research assistant in the department of pathology

Presbyterian Hospital Acquires Property—Presbyterian Hospital has recently purchased the property of the New York School for the Deaf on Riverside Drive just south of the Columbia-Presbyterian Medical Center The tract of seven acres is assessed at a valuation of \$1,775,000, according to the *New York Times* The purchase price was given to the hospital by an unnamed donor, it was said Plans for using the property have not been made public The school for the deaf, which has occupied the grounds since 1856, has purchased land in Greenvale, near White Plains in Westchester County, where it plans to erect a group of modern buildings

District Health Center Dedicated—The East Harlem Health and Teaching Center, first of eight district health centers to be opened this year as branches of the New York City Department of Health, was dedicated June 21, by Dr John L Rice, commissioner of health The district health center plan, by which the city's health services will be decentralized was begun in 1934 as the result of a survey conducted in 1929

by the Committee on Neighborhood Development and based on the experience of demonstration centers operated by the American Red Cross and the Milbank Memorial Fund A grant of \$2,107,797 was obtained from the Public Works Administration to construct the necessary buildings, of which the East Harlem unit is the first Seven others will be opened within the next four months, according to the *New York Times* The centers will be under the bureau of district health administration set up in 1934, each directed by a district health officer It is planned that thirty such centers will be completed by 1945 to carry out health service in all parts of the city In the East Harlem building are maternal and child health services, a tuberculosis clinic, social hygiene dental hygiene and health education services and facilities for instruction of medical students in public health work

OHIO

District Meetings—The annual summer meeting of the Eighth Council District of the Ohio State Medical Association was held at Rocky Glen Sanatorium, McConellsville, June 17, with the following speakers on the scientific program: Drs Myron Metzenbaum, Cleveland, on "Chronic Purulent Sinusitis and Its Relation to Secondary Pulmonary Complications", William N Taylor, Columbus, "Tuberculosis of the Kidneys", Walter G Stern, Cleveland, "Estimation of Disability from an Orthopedic Standpoint"—Drs Russel G Means, Columbus, and Frederick B Utley, Pittsburgh, were the guest speakers at a meeting of the Seventh Council District of the state association in Steubenville, May 27, on "Treatment of the Common Cold" and "Evaluation of Modern Methods of Treatment of Peptic Ulcer" respectively—At the summer meeting of the Sixth Council District at the Shady Hollow Country Club near Massillon, June 23, Dr Sidney M McCurdy, Columbus, medical supervisor for the State Industrial Commission, spoke on "Our Mutual Problems" and Dr Jonathan Forman, Columbus, "Allergy in General Practice"

Health Exhibit at the Cleveland Exposition—A health section arranged by the Cleveland Academy of Medicine for the Great Lakes Exposition has for its central feature the *Camp Transparent Woman*, made at the Hygiene Museum in Dresden, Germany, and brought to the United States recently by Mr S H Camp, Jackson, Mich Three hundred physicians and guests attended a preview ceremony June 15, at which the speakers were Drs John H J Upham, Columbus, President of the American Medical Association, Wingate Todd, Henry Willson, Payne professor of anatomy, Western Reserve University School of Medicine, Cleveland, Harold J Knapp, city health commissioner, and Mr Fred W Ramsey, city welfare director Dr John Dickenson, president of the academy of medicine, presided Other exhibits in the display include the progress of medicine, prepared by the American Medical Association, a full length x-ray film of the human body and other films by the Eastman Kodak Company, cardiovascular disease by the Metropolitan Life Insurance Company, undulant fever by the U S Public Health Service, "American Medicine—Past and Present," by the Cleveland Museum of Historical and Cultural Medicine, and models of the glands of internal secretion by the Cleveland Clinic Drs Hubert C King, Lakewood, Russell L Haden and Robert M Stecher made up the academy's committee that arranged the exhibit

OREGON

State Medical Meeting Dates Changed—The dates of the annual session of the Oregon State Medical Society have been changed from September 16-18 to October 21-23

PENNSYLVANIA

District Meetings—The Sixth Council District of the Medical Society of the State of Pennsylvania held its annual meeting at Philipsburg, May 13 Dr James A C Clarkson, Lewistown, who has been in practice fifty years and has been secretary of the Mifflin County Medical Society for thirty-eight years, was the guest of honor Speakers included Drs Hobart A Reumann, Philadelphia on "A Review of the Progress in Infectious Diseases", Lewis K Ferguson, Philadelphia "Treatment of Diseases of the Perinatal Region and Anal Canal" and Maxwell J Lick, Erie, president of the state society, "Health Fads and Fancies" Drs Frederick J Bishop, Scranton, president-elect of the state society, and Walter F Donaldson, Pittsburgh, secretary, discussed organization activities—The Seventh Council District held its annual meeting at Wilkesport May 14 Drs Maxwell J Lick, Erie, and Ferdinand Fetter, Philadelphia, discussed "Differential Diagnosis in Abdominal Tragedies" and "Fever Therapy" respectively

Philadelphia

Honorary Degrees—Dr George P Muller, professor of clinical surgery, Jefferson Medical College, received the honorary degree of doctor of science at the commencement exercises of Muhlenberg College, Allentown, June 8—Dr Chevalier Jackson received the honorary degree of doctor of philosophy at the annual commencement of Pennsylvania Military College, Chester, June 8—Dr Ross V Patterson, dean and Sutherland M Prevost professor of therapeutics, Jefferson Medical College, received the honorary degree of doctor of laws at commencement at Wake Forest College, Wake Forest, N C

Dr Donaldson Honored—Henry H Donaldson, Ph D, member of the Wistar Institute of Anatomy and Biology, received the honorary degree of doctor of science from Clark University, Worcester, Mass, June 5 A plaque of Dr Donaldson, sculptured by Dr R Tait McKenzie, was presented to the Lenape Club May 12, on the occasion of Dr Donaldson's eightieth birthday He has been president of the club for twenty years Dr Donaldson graduated from Yale University in 1879 and took the degree of doctor of philosophy at Johns Hopkins in 1885 He was a member of the faculty of Clark University for several years and became professor of neurology at the University of Chicago in 1892, remaining there until he joined the Wistar Institute in 1906 In 1916 he was president of the American Association of Anatomists

SOUTH CAROLINA

Personal—Dr James R Howell, Aiken has resigned as superintendent of the Aiken County Hospital—Dr William Fishburne, Monck's Corner, was elected president of the South Carolina Public Health Association at the annual meeting in Myrtle Beach in May

TENNESSEE

Society News—At a meeting of the West Tennessee Medical and Surgical Association in Paris May 20, the speakers included Drs Edwin W Coker, Memphis, on "Insulin in the Treatment of Certain Nervous and Mental Conditions" Harrison H Shoulders, Nashville, "Diagnosis of Acute Abdominal Conditions", Oval N Bryan, Nashville, "Diagnosis and Treatment of Syphilis," and J H Eugene Rosamond, Memphis, "Abstract of the Literature of 'Prontosil'"

Personal—Dr Oscar S Hawk, superintendent of the Tennessee Home and Training School for Feeble-minded Persons Donelson, has been appointed acting head of the Eastern State Hospital, Knoxville, it is reported—Dr Webster B Key, Memphis, has been appointed to the state public health council to succeed Dr John C Ayres, Memphis, resigned—Dr Fray O Pearson, Knoxville, has been appointed director of the Upper Cumberland health unit, comprising Fentress, Pickett, Clay, Overton and Jackson counties

TEXAS

Personal—Dr James H Stephenson, formerly superintendent of Parkland Hospital, Dallas, was appointed superintendent of Jefferson Davis Hospital, Houston, effective June 1 The hospital is to move into a new building about October 1—Dr Charles J Wagner, Lubbock, received the honorary degree of doctor of science at Monmouth College, Monmouth Ill, in June

VERMONT

Officers of State Board of Medical Registration—Dr Frank E Farmer, St Johnsbury, has been elected president of the Vermont State Board of Medical Registration Other officers are Drs Stanton S Eddy, Middlebury vice president, Winfield Scott Nay, Underhill, secretary, reelected, and George I Forbes, Burlington, treasurer Dr Nay was first appointed to the Vermont board in 1904

VIRGINIA

Professor of Military Science Appointed—Lieut-Col Edwin B Maynard, Medical Corps, U S Army, has been appointed professor of military science and tactics in the Medical Reserve Officers' Training Corps at the Medical College of Virginia Dr Maynard is a native of Virginia and was graduated from the University of Virginia Department of Medicine in 1908

Changes in Health Officials—Dr William Grossmann, Richmond, has been appointed epidemiologist in the bureau of communicable diseases of the state health department—Dr James N Dudley, formerly of Danville has been named health officer of Northampton County, with headquarters at Eastville He succeeds Dr Hugh B Magill Jr, who has gone to Hanover

County, with headquarters at Ashland Dr Linwood Farley, Ashland, recently in Hanover County, has been appointed assistant health officer of the Valley Health District, of which Dr Shockley D Gardner, Luray, is in charge

PUERTO RICO

University News—The School of Tropical Medicine of the University of Puerto Rico has recently acquired a parcel of land east of its buildings and will use it for an extension to the institution The University Hospital is undergoing reconstruction and will probably be reopened in about eight months

GENERAL

Orthopedic Board Examinations—The next meeting of the American Board of Orthopedic Surgery will be held in Los Angeles, Jan 14-15, 1938 Applications should be sent to the secretary, Dr Fremont A Chandler, 6 North Michigan Avenue, Chicago, on or before October 15 The board also announces that after October 1 the examination fee will be increased to \$50

Grant for Endocrine Research—The John and Marv R Markle Foundation, New York, has appropriated \$100,000 to the National Research Council for the support of research in endocrinology in the next three years The fund will be administered by the division of medical sciences and will be allotted in grants for approved programs of research in this field to be conducted in institutions which may wish to collaborate in the investigations, according to Science

Society News—The American Pharmaceutical Association will hold its eighty-fifth annual meeting in New York the week beginning August 16, with headquarters at the Hotel Pennsylvania—Dr William P Healy, New York was chosen president-elect of the American Radium Society at its annual meeting in Atlantic City, June 7-8—Dr Harry L Alexander, St Louis, was named president-elect of the Association for the Study of Allergy at the annual meeting in Atlantic City, June 7-8, Dr Warren T Vaughan, Richmond Va was elected vice president and Dr James Harvey Black, Dallas Texas, secretary

Pan American Medical Cruise—The seventh cruise congress of the Pan American Medical Association will take place January 15-31, on the *Queen of Bermuda* The group will spend four and a half days in Havana, where the main part of the congress will be held, three days of scientific sessions with operative clinics The cruise will continue to Port au Prince, Haiti, Trujillo City, Santo Domingo, and San Juan Puerto Rico Applications for reservations should be addressed to the Pan American Medical Association 745 Fifth Avenue New York The program committee will be pleased to receive applications for the presentation of scientific contributions, an announcement states

Meeting of Life Insurance Physicians—The twenty seventh annual meeting of the Medical Section of the American Life Convention was held in Colorado Springs, Colo, June 17-19 Among the speakers were

Dr Alexander Marble Boston Nondiabetic Glycosuria
Dr James Thornley Bowman London Ont Pregnancy and Its Complications
Dr James J Waring Denver Prognosis of Extrapulmonary Tuberculosis
Dr Alfred C Reed San Francisco Ultimate Prognosis of Hookworm Disease, Malaria and Amebiasis

Dr Walter E Thornton medical director of the Lincoln National Life, Fort Wayne, Ind, was elected chairman Dr Albert E Johann, Des Moines Iowa vice chairman and Dr Benjamin F Byrd, Nashville, Tenn, reelected secretary

Another Fraudulent Salesman—Physicians in Georgia and South Carolina have recently reported the activities of a salesman who claims to represent the "Atlas Sales Company" a salesman selling magazines, a medical dictionary and "National Medical Monographs," a six volume work Physicians paid from \$3 to \$8 for combinations of these publications One invoice sent to the American Medical Association is signed "S R Ray" and another with the initials "S R" Nothing was heard from the orders One physician wrote to the "Atlas Sales Company," the address of which was given as 1020 Walnut Street Philadelphia, and his letter was returned marked "no such company" The man was described in one report as about 50 years old, thin, about 5 feet 6 inches tall partly bald His hair was gray and he wore spectacles and was nervous In THE JOURNAL March 13, page 893 there was a warning of a fraudulent salesman for the same publications using the name J S Ray and claiming to represent the Continental Press, Chicago At that time the National Publishers' Association issued a bulletin stating that the Continental Press was nonexistent and

asking that physicians approached by the man wire immediately to Mr Frank Ware, National Publishers' Association 232 Madison Avenue New York

Proposed National Congress of Obstetrics and Gynecology—The *American Journal of Obstetrics* recently proposed editorially that a national congress of obstetrics and gynecology be organized in the United States, to be held possibly in 1939. Resolutions of endorsement have been approved by various national and sectional groups it was said and it has been suggested that preliminary arrangements be made by the American Committee on Maternal Welfare. Every practitioner of medicine interested in this branch as well as public health authorities and lay organizations that have contributed to the preparations for better maternity care should be reached in the call for this congress, it was observed. The editorial pointed out that the last International Congress of Obstetrics and Gynecology was held in Berlin in 1912 and that although one has been called in Amsterdam in 1938 disturbed conditions in Europe make it uncertain how much support the congress will receive.

Changes in Status of Licensure—The Oklahoma State Board of Medical Examiners recently reported the following actions taken at a meeting June 10

Drs Wade Calhoun Mitchell Henryetta John W McCrary McAlester William A Houser Durant George Washington Hill Ardmore licenses suspended for violation of the narcotic laws

Drs Glenn Waldow Zink Barnsdall Verner Ashton Hartman Post Texas and Clarence Andrew Griffin San Antonio Texas licenses revoked for violations of the narcotic laws

The New Jersey Board of Medical Examiners recently reported the following actions taken April 21

Dr Francesco Mandruzzato whose last known address was New York license revoked through his failure to present evidence that he had become an American citizen

The New York State Board of Medical Examiners recently reported the following action

Dr Jacob Joseph Seidenstein whose last known address was Brooklyn license revoked April 16 following conviction of a felony

The Massachusetts Board of Registration in Medicine announces the following action

Dr Roy L Garland Gloucester license revoked May 20 because of conviction in court on a charge of abortion

Dr Leslie A Burns Millers Falls license revoked May 20 because of repeated violation of the Harrison Narcotic Law and continued use of narcotics for other than therapeutic purposes

The Commission on Licensure in the District of Columbia reports the following action

Dr MacPherson Crichton Washington license revoked recently because of his conviction on the charge of performing an abortion he was sentenced to the penitentiary for from one year to eighteen months

The Eclectic State Medical Board of the State of Arkansas revoked the licenses of the following at its meeting, May 10, because it is said they were obtained by fraud and deception

Dr John M Betts Bloomfield N J
Dr Martin L Brockmeier St Louis
Dr Frank C Catanzaro St Louis
Dr Alva L Garner Devils Lake N D
Dr Leonard L Gramm Milwaukee

Medical Bills in Congress—*Changes in Status* A Senate amendment to H R 6652, making appropriations for the military establishment, has been agreed to by the House, increasing the medical corps of the army by fifty officers and the dental corps by twenty-five officers. The Senate Committee on Commerce held a hearing, July 8, on Senate 2067, proposing to authorize an annual appropriation of \$1,000,000 to enable the Surgeon General of the Public Health Service (1) to study and investigate the cause treatment and prevention of cancer and (2) to cooperate with the state boards or departments of health for the prevention, control and eradication of cancer within the states. H R 4716 has been reported to the Senate, without amendment, proposing an appropriation of \$1,500,000 to erect a marine hospital in Florida, the site to be selected by the Federal Board of Hospitalization. H R 6283 has been reported to the House, with amendments, proposing to increase the punishment of second, third and subsequent offenders against the narcotic laws. H R 6547 has passed the House, proposing to authorize an appropriation of \$4,850,000, to enable the Secretary of the Navy to construct in the District of Columbia, or in the immediate vicinity thereof, buildings to replace the present Naval Hospital and Naval Medical School, including facilities for the Naval Medical Center and Naval Dental School. *Bills Introduced* Senator Robinson Arkansas, has submitted in the Senate an amendment to be proposed by him to the third deficiency appropriation bill, proposing to make available to the United States Public Health Service the sum of \$189,000 for the maintenance and expenses of the Division of Venereal Diseases, a part of which is to be expended for

additional facilities and services at the Hot Springs Transient Medical Center and Infirmary. Senate 2731, introduced by Senator Nye, North Dakota, proposes to protect the public health by regulating the importation of dairy products into the United States. Senate 2746, introduced by Senator Robinson, Arkansas, proposes to authorize an initial appropriation of \$5,000,000 and for each fiscal year for four consecutive years a sum "sufficient to carry out the purposes of this act" to enable each state to make adequate provision for hospital beds for tuberculous patients. The sums to be appropriated are to be administered by the Surgeon General of the Public Health Service.

FOREIGN

Personal—Sir Frederick Gowland Hopkins, professor of biochemistry, University of Cambridge, has recently been awarded the Harben gold medal of the Royal Institute of Public Health. The medal is awarded every three years to the person considered to have done most to aid public health.

Memorial to Noguchi and Young—The *Lancet* reports that the government of the Gold Coast, West Africa is erecting a memorial to Drs Hideyo Noguchi and William Alexander Young, who died there of yellow fever in 1928 while working at the Medical Research Institute in Accra. In their memory a bronze tablet is to be placed in a room at the institute and a small drinking fountain in front of the outpatient division of the Gold Coast Hospital.

Prize for Essay on Tuberculosis—The International Union Against Tuberculosis announces that a biennial prize of 2,500 francs has been established in memory of the late Dr Leon Bernard, founder and for many years secretary-general of the union. The prize will be awarded for the first time in 1938 to the author of an original essay on the social aspect of tuberculosis written in French or English. Essays must be typewritten or printed, must not exceed 10,000 words and must be sent before May 1, 1938, by a government or an association belonging to the union to the secretariat, 66 Boulevard Saint-Michel, Paris (VI).

Government Services

New Director of Maternal and Child Health Division

Dr Edwin F Daily, assistant director of the maternal and child health division of the Children's Bureau has been appointed director. Dr Daily, a graduate of the University of Colorado School of Medicine in 1929 was formerly on the staff of the department of obstetrics and gynecology of the School of Medicine, Division of Biological Sciences University of Chicago. He will be in charge of the administration of the maternal and child health provisions of the Social Security Act.

Changes in Public Health Service

The U S Public Health Service announces the following changes among others

Medical Director Dana E Robinson relieved at Montreal Canada and assigned to Paris France where he will be in supervisory charge of service activities in Europe in connection with the medical examination of aliens at selected ports of Great Britain Ireland Irish Free State and continental Europe and the enforcement of quarantine laws and regulations applicable to ships and personnel destined to ports of the United States.

Medical Director Claude C Pierce relieved at Paris and assigned to New York to assume charge as director of public health service district 1 comprising the states of Maine New Hampshire Vermont Massachusetts Rhode Island Connecticut New York and New Jersey and in addition to act as regional consultant of district 1 in connection with disease and sanitation investigations in the New England states.

Asst Surg Wilfred N Sisk relieved at Boston and assigned to Nashville for duty with the Tennessee State Department of Health to assist in public health administration activities.

Surg Estella Ford Warner relieved at Washington D C and assigned to Albuquerque N M for duty in connection with the supervision of administrative affairs concerning the control of communicable diseases among the Indians.

Passed Asst Surg David C Elliott relieved at Hagerstown Md and assigned to Springfield Ill for advisory duty at the Illinois State Department of Health in connection with venereal disease control activities.

Sr Surg James F Worley relieved at San Francisco and assigned at Juneau Alaska for duty in connection with the control of communicable diseases among the Indians.

Surg Erval R Coffey relieved at Seattle and assigned to New York to assume charge of the regional office for district 1.

Dr Richard H Smith resident at U S Marine Hospital Ellis Island appointed and commissioned as assistant surgeon in the Recrue Corps for active duty.

The Capitation Fee

The Insurance Acts Committee of the British Medical Association made a claim that the changes which have taken place since 1924, when the present capitation fee of 9 shillings (about \$2) per insured person was awarded, justify an increase of about a third. The Ministry of Health did not agree and a court of inquiry was appointed, at which lengthy arguments were brought forward on both sides. For the association it was pointed out that there had been "a reorientation of medical thought and a widening of the basis of medical practice," which now seeks not only to remove disease conditions but to promote health. The advance of medical science had increased the complexity of diagnosis and treatment. Since 1924 the average number of attendances per insured person had increased from 375 to 502. The proportion of elderly persons in the population had increased, and it was claimed that an important contributory factor in this was the constant medical attention they were able to command. In turn they required more medical treatment. Practice expenses in the form of rates, taxes, the employing of assistants, and traveling costs had increased.

For the Ministry of Health, evidence was given by its medical inspectors disputing these arguments. The ministry's own calculations showed that, while the number of office attendances increased by 107 per cent, the number of visits fell by 38. To estimate the net effect, visits and attendances were weighted in the proportion of $1\frac{1}{2}$ to 1 (according to the fees charged in private practice). The result was a net increase in services rendered of 35 per cent. With regard to the advances in medical science, the evidence for the ministry was that improved methods have mainly affected specialist practice and that such methods as have been adopted in general practice, for example the injection of varicose veins, have tended to reduce the total services required. Similarly, a great amount of work used to be thrown on the practitioner by cases of chronic dyspepsia or gastritis. Today the condition of these patients was diagnosed quickly and they were operated on or treated medically and in the majority of cases made good recoveries.

The court of inquiry reported that the present capitation fee of 9 shillings should be maintained, but the British Medical Association scored a success on one point. It has been decided to extend insurance to juveniles who leave school at 14 and enter insurable occupations. At present they do not come under the insurance act until the age of 16. For these the Ministry of Health offered first a smaller capitation fee than that paid for adults on the ground that they would make less demand on medical services than older persons and, secondly, did not require certification. They now claimed that half the adult fee was the appropriate rate. The court reported in favor of the full rate of 9 shillings for juveniles.

Physical Training and Recreation Bill Passed

The Physical Training and Recreation Bill has passed its third reading in the House of Commons. Local organization is in progress and a propaganda campaign will be started in the autumn. The aim is to build up a new leadership to train men and women and to inspire the whole nation with the ideal of personal fitness. Every child is to have access to physical education. Work in this direction has already been done by the National Playing Fields Association, which has helped to provide 1,600 playing fields and spaces during the twelve years of its existence. Most of these are in the industrial areas, where the need is greatest. Their aim is not mass drill formation but to develop the desire for physical health and recreation by encouraging the playing of team games, which develop

mental activity as well. They would rather have a million people doing 100 yards in twelve or thirteen seconds than a few sprinters doing it under ten.

Injuries of Peripheral Nerves

In civil practice, injuries of peripheral nerves which require surgical operation are infrequent, but the war gave rise to considerable experience of this kind. At the Royal Society of Medicine Mr. Harry Platt, an orthopedic surgeon, in opening a discussion on injuries of peripheral nerves stated that he had performed 510 peripheral nerve operations between March 1915 and December 1920, but during his civil practice in 1931-1936 only eighty-nine. A considerable proportion of the nerve injuries of civil life never reached the operating theater. He divided these injuries into three groups: (1) nerve injuries accompanying fractures and dislocations, (2) nerve injuries due to penetrating wounds, (3) traction injuries of the brachial plexus. The first group was subdivided into the following:

(a) Dislocations and fracture dislocations of the shoulder joint. Circumflex palsy occurred in about 5 per cent of all subcoracoid dislocations reduced promptly and efficiently. As the head of the humerus is thrust downward toward the axilla, the nerve is suddenly overstretched but rarely, if ever, completely ruptured. Under relaxation and reeducation recovery from the deltoid palsy usually takes place in three or four months. Total and permanent deltoid palsy, indicating complete rupture of the nerve, is almost unknown and must be regarded as beyond repair.

Damage of one or more of the infraclavicular plexus trunks may be sustained at the time of the dislocation or may develop later in an unreduced dislocation or fracture dislocation. The full effects of a severe plexus lesion are rarely demonstrable during the first week. The more spectacular wrist drop may mask coexisting palsy of the intrinsic muscles of the hand. The prognosis of primary lesions of the plexus trunks is not unfavorable. From posterior cord lesions, recovery within three to six months is the rule. For the inner cord recovery is much more prolonged and usually is incomplete. Experience of conservative treatment has convinced Mr. Platt that no advantage is to be gained from exploration in the early stage. In secondary lesions due to an unreduced dislocation, recovery is prevented by the strangling effects of scar tissue, which forms round the dislocated head. The nerve trunks should be freed without delay.

(b) Musculospiral lesions in fracture of the humerus. These may be primary (from direct impact of a bony fragment) or secondary (from adherence of the nerve to bone). The majority of lesions accompanying simple fracture undergo spontaneous recovery. Hence treatment should be conservative for three or four months. If after this signs of complete block still persist, the nerve should be explored.

(c) Nerve lesions in fractures and dislocations of the elbow. Lesions of the ulnar nerve are predominant. They are incomplete and usually recover under conservative treatment. In a minority, severe progressive neuritis occurs and demands neurolysis with transportation of the nerve to the front of the joint. The median nerve is rarely implicated. In mild cases the treatment is conservative, in graver lesions early neurolysis is desirable.

(d) External popliteal lesions in ligamentous rupture of the knee. These lesions are not common, during the last fifteen years Mr. Platt has operated in seven cases. In five cases a complete lesion with extensive gap was discovered and end to end suture performed. Three patients showed useful recovery of function, and failure was complete in the other cases.

Group 2. Nerve injuries due to penetrating wounds. In the upper limb these injuries are rare above the level of the lower third of the forearm. In cases of division of the median or ulnar nerve, if the wound is small and reasonably clean, primary suture may be practiced with safety. In more extensive

wounds with widespread bruising and multiple tendon injuries and in infected wounds, it is better to postpone repair of the nerve lesion until the wound conditions are more favorable.

Group 3 Traction lesions of the brachial plexus. These take two forms: (a) traction lesions of the infant during difficult labor, (b) traction lesions in the adult, usually due to road accidents. The majority of cases of birth palsy show spontaneous recovery of various degrees in the first few months. Imperfect recovery, with defective growth of the limb, is the rule. Operations have little to offer. In the past twenty years 300 cases have come under Mr. Platt's observation and in only ten has he felt compelled to explore the plexus. In two cases of resection and suture of the upper trunk, partial recovery of the upper arm muscles occurred. In a resection and suture of all three supraclavicular trunks there was excellent recovery in the upper-arm group but complete failure in the lower-arm group. In the remaining seven cases, nerve trunks barely recognizable, but obviously intact, were disentangled from scar tissue, or irreparable lesions were disclosed. The effects of the neurolysis were negligible.

The majority of traction lesions in the adult are not amenable to surgical repair and they may be completely inaccessible. But the opportunity occasionally arises for repair of a circumscribed lesion of one or more trunks. The main value of operation is in ascertaining the extent of the lesion. Thus in one case complete avulsion of the upper and middle trunk at the level of the intervertebral foramina—an irreparable lesion—was discovered. This information enabled a long period of splinting in abduction to be adopted and physical treatment of the forearm and hand to be concentrated on, resulting in considerable recovery of function.

PARIS

(From Our Regular Correspondent)

June 10, 1937

Treatment of Schizophrenia by Insulin Shock

Prof. Henri Claude, head of the department of psychiatry in the University of Paris, and Dr. P. Rubenovitch of Paris reported their technique in the treatment of the schizophrenic syndrome by insulin shock in the February 15 issue of *Semaine des hôpitaux de Paris*. They gave a daily injection, early in the morning before breakfast, for five days successively, followed by a two days interval during which nothing was given. The initial dose varied from 5 to 15 units according to the physical condition and weight of the patient, then the dose was increased 5 units daily. A personnel trained in watching for symptoms of hypoglycemia is indispensable. The attendants should be near the patient and close to a laboratory. The treatment room ought to be completely isolated in order that the treatment may be given in an atmosphere free from all noise. The treatment having been completed, the patients ought not to be sent back to the wards. They should continue treatment in an environment where occupational therapy is available.

As a result of the treatment, an improvement of the strength, appetite and sleep are noted. In two patients an oliguria appeared which gave rise to much concern. In two others, menstruation returned, after a suppression of several months. The mortality in Vienna and Switzerland is quoted as being 3 per cent. Although the treatment is not without its dangers, it merits trial in certain schizophrenic states if given in a hospital and under the strictest surveillance.

Legal Responsibility in Industrial Medicine

Two interesting decisions have been recently announced on the responsibility when a worker selects his own physician to care for an injury received while engaged in his usual factory occupation. In one case the treatment given the worker aggravated the injury and a suit was brought to determine whether the physician or the employer was responsible. Accord-

ing to the law of 1908, an injured worker has the right to be treated by any physician whom he chooses.

The two courts before which this test case was brought rendered practically identical decisions. The court at Beziers, Nov. 20, 1934, decided an injured worker is not able to claim damages from a physician for any malpractice that has made the injury worse because of unskilful treatment. It is impossible, according to the decision, to distinguish between the effects of the original injury and those resulting from improper care. The latter must be considered as a direct and immediate consequence of the accident, hence such sequels must be paid for by the employer or his insurance company.

In the second test case, the question submitted was whether the employer (or his insurance company) could claim damages from the attending physician for unskilful care of an injured employee. The Nantes court decision denied the responsibility of physicians under such conditions. A physician called to care for a patient injured in an industrial accident cannot be considered as liable either to the employer or to the employee. The physician's care of such an accident cannot be dispensed with and the law has provided for its being given to an injured employee. The latter has the right to choose his own medical attendant for an industrial accident, hence the surgical or medical care constitutes an indivisible entity with the accident and its consequences. As a result, the employer or his insurance company is not entitled to bring action against the employee's physician even though the treatment has not conformed with what the law considers reasonable care and skill.

Society of Hydrology and Medical Climatology

The annual meeting of the Society of Hydrology and Medical Climatology was held March 1. The first paper was by Guy Laroche and Grigaut of Paris on "Our Present Knowledge of Cholesterolemia and Its Clinical Importance." Cholesterolemia should be regarded as a part of lipemia and not as an independent condition. The cholesterol content of the blood (by the Grigaut method) in young adults is from 16 to 18 Gm., and any figures above 2 Gm. must be regarded as abnormal. Hypercholesterolemia as found in rickets, infections, hyperthyroidism, Addison's disease and advanced hepatic cirrhoses was described. Hypercholesterolemias can be divided into three principal groups. In the first group are those observed in chronic nephritis and nephrosis, diabetes, myxedema and disturbances of nutrition (gout, urinary lithiasis and arteritis). These diseases are accompanied by excess of lipids in the blood and adrenals and an increase in the ratio of cholesterol esters to total normal blood cholesterol. In the second group may be placed hypercholesterolemia due to hepatic dysfunctions. Here no reaction on the part of the adrenals exists and the ratio of cholesterol esters to total normal cholesterol is decreased. This type is seen in retention icterus, biliary lithiasis and xanthoma of hepatic origin. The third group is less sharply defined and includes hypercholesterolemia in plethora and in sedentary and asthmatic patients.

The second paper was by Tixer, Seze and Eck, on treatment of diseases due to hypercholesterolemia. There is often discordance between the blood cholesterol content and the clinical picture whether modified by treatment or not. In such instances the dermal reaction to cholesterol as suggested by Loeper is of considerable value. In attempting to treat hypercholesterolemia, it is necessary to employ opotherapy, chemotherapy and phytotherapy successively in conjunction with, vasodilators, diuretics, tonic-cardiacs and hydrotherapy.

In the third paper G. Binet reported a hypercholesterolemia in from 85 to 90 per cent of all patients suffering from liver disease, sent to Vichy. High blood cholesterol values are less often observed in uncomplicated biliary disorders than in those accompanied by disturbances of nutrition, such as diabetes, gout or plethora. The treatment at Vichy has a distinct beneficial influence on the hypercholesterolemia in from 80 to 85

per cent of the patients. Often weeks or months must elapse before the result can be evaluated. Certain waters, they believe, have a distinct cholagogue action by modifying the biliary pH , disinfecting the bile and thus opposing precipitation of cholesterol.

Conflicts Between Attending Physicians and Social Insurance Inspectors

One of the most disagreeable features of the present social insurance law is the interference of the representatives, both medical and lay, of the caisses, or compensation bureaus of the social insurance organization, in the treatment of a patient by the attending physician. Such interference consists in criticism of both the diagnosis and the treatment when the attending physician is absent, thus disrupting the necessary confidence that must exist between patient and physician.

The following case is cited in the May 9 *Concours medical*. The attending physician advised a patient to resume work. The medical inspector visited her without the attending physician's knowledge and told her that, although she was better, resumption of work was inadvisable. The attending physician felt that such a visit to the insured without his knowledge was unethical. In the answer to this complaint, a paragraph in the modified (1936) law is cited, according to which medical inspectors are responsible for surveillance of all social insured persons and are authorized to carry out any investigation regarding the condition of the insured. But it is formally forbidden that a medical inspector should interfere in the patient-doctor relationship. Under no circumstances should the diagnosis or merit of the treatment be discussed in the presence of the patient. If the medical inspector disagrees with the diagnosis and treatment, he must address himself to the attending physician and also make his report and criticisms to the caisse or compensation bureau to which he is attached.

In the case cited, the medical inspector evidently violated the regulations in informing the patient that she was not cured and not able to resume work.

May 27, 1937

Investigation of an Epidemic of Scarlet Fever

In Pinneberg, a town of some 9,000 population near Hamburg, a number of children and adults became suddenly ill with moderately severe scarlet fever about the middle of April. The cause of this outbreak at first eluded the investigators, there had been no large meetings of townspeople and it was vacation time in the schools. The epidemic appeared with explosive suddenness and attacked the most disparate groups. Within the course of a single week, 225 unequivocal cases were reported. There were two fatalities. The local health department finally found that the path of the epidemic coincided fairly well with the customer route of a certain milkman. Certain nonresidents of Pinneberg, for example, who had been visiting the town just prior to the outbreak and who had partaken of milk from the source in question also came down with the disease. When the milk supply from this source was stopped by the authorities the number of new scarlet fever cases dropped immediately and the epidemic came to a virtual end. Diseased cattle were in no way responsible for the contamination, but the milkman himself was found to have an undiagnosed scarlatinal infection accompanied by otitis.

Conservative and Operative Treatment of Goiter

Dr. Breitner, professor of surgery at the University of Innsbruck, Tyrol, discussed conservative and operative treatment of goiter before the Frankfurt Medical Society. The high incidence of goiter in the Tyrol lends itself well to this study. He finds it relatively easy to separate goiter into two groups on the basis of therapeutic indications: conservative or operative. Any goiter that causes mechanical disturbances will

require operative treatment. In intrathoracic goiter operative treatment is unqualifiedly indicated and it is only a question of which type of intervention should be attempted. Conservative iodotherapy is preferable to operation only in diffuse goiters of young children and adolescents. The fundamental differentiation of diffuse, nodular and mixed goiters (a decisive point in indicating the type of treatment) involves the peculiar character of general thyroid enlargements. The problem of selecting a suitable therapy lies in the diversity of forms which general enlargement may assume. Nodular goiter should remain untouched only in the absence of any symptoms. Elsewhere conservative treatment has not proved successful in pure struma adenomatosa, but goitrous nodules in a diffuse struma are favorably influenced by medication.

Goiters may be differentiated on a morphologic basis as set forth in the accompanying table.

Four Types of Goiter

Normal formation of secretion	All secretion is quickly excreted	Struma parenchymatosa
Normal formation of secretion	Most of the secretion retained	Struma colloidosa type I
Increased secretion	All excess secretion quickly excreted	Struma basedowiana (toxic goiter)
Near or complete cessation of secretion	Complete retention of secretion	Struma colloidosa type II

Each of these four types represents a pathologic alteration of function which needs to be restored to normal. When exaggerated excretion is present, iodine will be found most effective in curtailing the output. Iodotherapy can serve both to check an excessive excretion and to induce a more liberal secretion in suppressed states.

Diffuse goiter of youth is struma parenchymatosa with increased production and elimination. The results of iodotherapy are usually favorable. Operative treatment is indicated in the presence of mechanical disturbances. There should be postoperative systematic administration of thyroid for from six months to a year so that by compensation of the deficient secretion a recurrence may be prevented. Three types of hyperthyroidism can be differentiated: the psychogenic exophthalmic goiter, the iodine toxic goiter and the toxic goiter of endocrine origin. The standard routine calls for preliminary treatment with iodine (following Plummer's method) prior to operation. Toxic adenoma is refractory to iodotherapy and may even be aggravated by it. Breitner's observations indicate that no one system of therapy guarantees the favorable outcome of a given case.

Spatial Representation in the Roentgenogram

Spatial visualization of a physiologic process offers great difficulties. It is well known how much effort was entailed fifty years ago before the mechanics of the human gait could be established with anything like mathematical exactitude. The plastic visualization of motor processes was easy; the difficulty lay precisely in three-dimensional representation. Meanwhile the technic has been greatly improved. Cinematography, slow motion photography and roentgenography, especially the two first named, permit complicated motor processes to be represented with exactitude. Nevertheless the scientific knowledge of the human gait, of the statistics and mechanics of the human body have not been substantially augmented. As Dr. H. Koehnle demonstrated to the Dusseldorf Medical Society, the sectional x-ray visualizations of the human body can now be made not only in normal projection but in the third dimension. The ultimate aim is, however, to portray the spatial visualization of a particular region of the body as apart from the x-ray visualization of the organism as a whole and to study the mechanics of this region at rest and in movement. Koehnle has succeeded, using apparatus perfected by himself, in portraying the entire body both in visible light and by x-rays while the spatial position remained unchanged. The exposures

were also submitted to photogrammetric evaluation by means of special apparatus. Differences in bodily attitudes (during a given movement) are important, these vary among normal persons and persons affected with rigidity of the vertebral column or rigid and shortened feet.

Is Removal of the Tonsils Injurious?

Dr Eigler recently submitted a report of investigations undertaken at the Koenigsberg clinic on the late deleterious effects of removal of the palatine or pharyngeal tonsils. In no instance were permanent changes in the hematogram or impairment of the endocrine organs observed. The view is prevalent that the lymphatic pharyngeal ring offers protection against infection. There are two opposing theories of this defense mechanism. According to the newer theory, as formulated by Linck and Digby, the pathogenic micro organisms continually enter the adenoid tissue, there to be destroyed. This process leads to the formation of antibodies that are carried into the circulation. Patients who possess a susceptibility to pharyngitis, laryngitis and bronchitis furnish a reliable indication for tonsillectomy. In the presence of a well developed laryngitis granularis or pharyngitis sicca, tonsillectomy is contraindicated unless life itself is endangered. Then too in the treatment of singers and lecturers the physician must be especially careful in determining the indication for tonsillectomy, since the intervention might be followed by modifications of the vocal resonance.

AUSTRALIA

May 17, 1937

The National Health

There seems little doubt that our descendants will look back on our boasted Australian civilization, with its comparatively high incidence of tuberculosis, its high cancer rate, numerous acute and chronic diseases, its relatively high maternal and infantile mortality, its infectious diseases, and its epidemics of influenza, to say nothing of the more serious common cold, with the same sort of tolerant pity with which we regard our ancestors of the middle ages. This was a dominant note of the Ann Mackenzie oration delivered at the Institute of Anatomy, Canberra, this month by Harold Dew, professor of surgery at the University of Sydney. 'It is a lamentable fact,' he said, 'that the average standard of health in Australia is much below what it should be. Australia has an almost unequalled climate and an abundant supply of fresh food. Its people came from a comparatively hardy and vigorous stock. Health should be the right of every citizen but it is a tragic fact that a large proportion of the population rarely exhibit that glowing radiant appearance which denotes perfect health.' Professor Dew said that in New South Wales in recent years the average number of patients attending public hospitals was 26 per cent of the whole population. The figure for South Australia was 36 per cent, while those of the other states were somewhat smaller, but they all took no regard of the number of patients seen by private doctors. 'There is far too much chronic ill health,' he said, 'much of which could be controlled or prevented. The degree of suffering and the amount of time lost from work, and the lessening of national efficiency from that cause is beyond computation. The death rate must be greatly reduced and there is no reason why Australia should not build up the highest average national health standard in the world.' The formation of the Commonwealth Council for National Health and Medical Research has recognized the essential need for education of the people on health matters, by every possible modern method. The council has recommended the granting of financial aid for research work, and it has plans for appointing junior research workers for three year periods at a good salary from which senior research workers will be chosen, given permanent positions and employed on special work.

Foundation of Queensland Medical School

The inauguration of the Faculty of Medicine in the University of Queensland marks a new step in the progress of medical education in Australia. As roughly a half of the area of Queensland lies in the tropics, a feature of this medical course will be the inclusion of tropical hygiene and medicine as a compulsory subject in the undergraduate course. It is fifty years since a medical school was founded in Australia, the last being that in Adelaide, which was opened in 1885 and which has just celebrated its jubilee. The school in Melbourne, opened in 1863 was the first to be established in Australia. The Sydney school was opened twenty years later in 1883. At the present time the number of medical students in Sydney is 632, in Melbourne 609 and in Adelaide 120. It is expected that about forty students in each year will enter the Queensland Medical School making a total of over 200 medical students in all. In order to be admitted as an undergraduate to the Medical School of the University of Queensland, a preliminary educational standard known as matriculation is required. In framing the requirements for matriculation, the aim has been to encourage future medical students in their general education to study those subjects which will best fit them for entrance into the faculty. A notable deviation from the usual practice is that Latin is no longer compulsory, but a choice can be made between French and German. The study of German is recommended because it enables the medical student to gain access to the greatest volume of medical literature written outside their own tongue. Mathematics is compulsory, also both physics and chemistry, although only one of the latter two need be taken at the senior standard. The medical school is fortunate in having in Brisbane a 600 bed hospital comprising all the institutions necessary for the education of medical students. The Brisbane hospital includes a children's hospital, a modern maternity hospital and a hospital for infectious diseases, as well as providing all the usual training facilities of a general hospital. In the three other medical schools of Australia these various departments are scattered about in different places in a large city, and much time is wasted by the students in moving about from one to the other. The recommendations of the recent report of the British committee which studied the medical curriculum have been embodied in the curriculum adopted at the University of Queensland. Prof. H. J. Wilkinson is the dean of the Faculty of Medicine and professor of anatomy. Professor Wilkinson has relinquished a professorship in the Adelaide University to be the foundation dean of the Queensland Medical School. Prof. H. K. Lee is the professor of physiology. Australia as a whole is rightly developing a national spirit, but it is beginning to be recognized that Queensland presents problems peculiar to itself, which needs more determined and extensive study along certain and well defined lines. Sir Raphael Cilento has been appointed honorary professor of social and tropical medicine. Professors of pathology and obstetrics as well as lecturers in bacteriology, medicine, surgery, public health and preventive medicine have yet to be made. The first students will graduate in December 1940. The educational facilities of the Queensland Medical School will be comparable with those available in other Australian medical schools. Moreover, the experience gained by other Australian medical schools will be useful in avoiding many mistakes which are inherent in the development of an organization of this scope. Such a standard of medical training will be aimed at that reciprocity in medical registration will be sought from the general council of Great Britain. The future of this school will be worthy of being watched with great interest.

Physical Education in New Zealand

The national campaigns for improved physical fitness and nutrition in the older countries of Europe have had their effect on administrative thought in this part of the world. The New

Zealand government has drawn up plans for a national council of sport, the object of which is to encourage and develop all sports with the cooperation of all the sporting bodies in New Zealand, and the coordination of their activities. The New Zealand government recognizes that the foundation of the system of national physical well being must be the schools. The children will be taught real physical education, including something about their own physical make up. The national sport council would control the physical education and instruction of children while they are at school. The existing sports organizations would not be interfered with. Provincial councils would be formed, representative of all sports. The task of providing national playgrounds would be handled by the national council, which would control all gymnasiums, swimming baths, places for education and instruction and libraries, and would also organize parades and demonstrations of physical fitness.

Effect of New Zealand Traffic Code

Last July a strict traffic code was introduced in New Zealand, the chief feature of which has been that the speed limit of 30 miles an hour is enforced in "built up" areas. It is considered that this has been responsible for the marked reduction of accidents. The saving of lives since the campaign started in July has been at the rate of 100 a year when comparison is made with other years. Although the total of all traffic deaths has been substantially reduced in the last few months, the death rate among motor cyclists remains constant. They were involved in nearly a fourth of the fatal road accidents. The problem of the intoxicated driver still exists, but a more serious attitude toward this menace is being adopted.

Creation of a Ministry of Health

Apropos of the creation of the Ministry of Health, Rene Sand has outlined for the Societe medicale belge d'education physique the role that the new department will play in the development of curative and preventive social medicine, a role that will make of it the veritable complement of previously existing medical legislation. Social diagnostics is the complement of medical diagnostics; social medicine completes the treatment. It is obviously not for the physician to conduct the social investigation or to apply the "social" remedy. Social medicine is poorly understood by the physician, since he does not perceive in the aggregate the medical problems of his country. To solve these problems will be the task of the Ministry of Public Health. To broaden the new department's sphere of activity there have been brought together under it the bureaus of sanitation, of welfare, of physical education and of health. Its resources will consist of 55,000,000 francs in the ordinary budget (namely, less than 0.5 per cent of the state budget) and 100,000,000 francs in the extraordinary budget. Recognizing the need for establishing better coordination of various departmental functions having to do with medical, hygienic or social problems, the minister has organized an interministerial committee for health activities. Sand described the tasks and duties already accomplished and concluded his noteworthy report by sketching the program of the new Ministry of Public Health, which includes plans for the construction of playgrounds, field houses and natatoriums.

The Campaign of the Academie Against Alcoholism

The Academie royale de medecine de Belgique has transmitted to the minister of public health the text of a motion unanimously adopted by those present and having for its objective the continuation in force of legislation against alcoholism. The text reads as follows. In conformity with its previous utterances in the matter of the necessity for a vigorous fight against alcoholism, the Academie royale de medecine disap-

proves categorically of any restoration of the legal right to the consumption of spirituous beverages in public places. The Academie regrets that from time to time attempts are made to exact from parliament repeal of legislation which possesses a high moral significance and the effects of which have been salutary. The Academie hopes that in future the concept that, of all the duties incumbent on the state, the most important is that of protecting the race against the forces of moral degradation and physical deterioration, will cease to be contested.

Health Supervision of Youthful Workers

Health supervision of employees under 18 years of age has been instituted in industrial and commercial establishments by the Labor Medical Service. This supervision consists chiefly of medical examinations undertaken according to the following routine: (1) an examination of each worker during the first month of employment, (2) a general annual check up and (3) special follow ups of young workers whose state of health has been judged precarious on previous examination. These follow ups may be semiannual, quarterly or monthly according to the decision of the medical inspector.

Employers are compelled to cooperate with the medical officers in order that the health supervision may function as smoothly as possible. The principal duties of employers in this connection are: 1 Maintenance of an up to date list, in conformity with the model prescribed by the health service, of all employees under the age of 18. This list may be requisitioned at any time by the regular medical inspectors or their superiors. 2 Notification of the medical inspector within two weeks following the employment of any person less than 18 years of age. 3 Reporting to the medical inspector the frequent absence on account of illness or the chronic ill health of any young employee. 4 Provision of the examining medical officers at the time of their visits with quarters that are suitably lighted, ventilated, heated during cold weather and equipped in a way that will assure the swift and decent conduct of the examinations. 5 Full compensation of the employee for time lost from work on account of medical inspections. 6 Compliance with the recommendations of the medical officer in the matter of the type of work assigned to the individual adolescent employee. This will safeguard the physical development of youths known to be in delicate health. 7 Communication to the Labor Medical Service of all information requested by it with regard to decisions in particular cases.

The medical examinations mentioned under article 1 take place at the expense of the employers and are carried on by physicians selected by the employers and approved by the minister of labor and the Prevoyance sociale. Examination will take place either at the doctor's office or in suitable quarters on the firm's premises placed at the doctor's disposal.

The results of these medical examinations shall be entered in the "carnets sanitaires" (individual pocket health cards) of the employees in question. A "carnet sanitaire" is made out by the employer following the initial medical examination of any employee who does not already possess such a card.

Substitutes for Dairy Products

In the face of the increasing importation of foreign substitutes for dairy products, a law has just been passed which prohibits the importation, manufacture or preparation of the following classes of substitute products: (1) artificial emulsions of fatty or oily foodstuffs that are susceptible of being utilized as substitutes for whole milk or for the liquid derivatives of whole milk, (2) reconstituted milks, (3) products suitable for human alimentation that contain pectin, gelatin, gelose, gums and other thickening agents similar to whole milk or its liquid derivatives and (4) cheeses the fatty ingredients of which are partially or totally composed of substances foreign to milk, or of grease obtained from butter by some purifying or refining process.

Marriages

EDWARD RHODES STITT, Surgeon General, Rear Admiral, U S Navy, retired, Norfolk, Va, to Mrs James Thornwell Newton, May 3

JOHN LYON CAUGHY JR, New York, to Miss Winnifred Emily Scott of Auburndale, Mass, May 22

REGINALD CHARLES FARROW, Newark, N J, to Miss Carolyn Tyler Chase of Hartford, Conn, June 18

ROBERT H GELDER, Winthrop, N Y, to Miss Mary Wisdom Zirkle of Kingston, Tenn, May 8

CHARLES W REAVIS, Richmond, Va, to Miss Allie Virginia Cheek of Warm Springs, May 20

GLENN T SCOTT JR, Memphis, Tenn, to Miss Frances Lawrence of Barlow, Ky, recently

DONALD PAUL BIRD, Lakeland, Fla, to Miss Mildred Elaine Lewis in Bartow, April 17

Deaths

John Randolph Winslow, Baltimore University of Maryland School of Medicine, Baltimore 1888 member and formerly historian of the Medical and Chirurgical Faculty of Maryland fellow of the American College of Surgeons professor emeritus of rhinology and laryngology at his alma mater, professor, 1913-1921, and clinical professor of nose and throat diseases, 1903-1913, lecturer on chemistry 1888-1889, professor of physiology, 1889-1894, Woman's Medical College, Baltimore for many years surgeon to the Baltimore Eye Ear and Throat Hospital and throat surgeon to the Presbyterian Eye, Ear and Throat Hospital, aged 71, died, June 26 of chronic myocarditis

Russell Edward Stone, New Orleans, Vanderbilt University School of Medicine, Nashville, Tenn, 1899, member of the Louisiana State Medical Society, fellow of the American College of Surgeons, since 1931 professor of clinical surgery, Graduate School, Louisiana State University, served during the World War, aged 58, chief of the surgical service of the Woman's Hospital, senior visiting surgeon to the Charity Hospital, senior associate surgeon to the Touro Infirmary, where he died, June 18, of complications following an operation for appendicitis

Hugh Allison Greenwood Ⓢ Maracabo, Venezuela, South America, Tulane University of Louisiana Medical Department, New Orleans, 1907, member of the Medical Association of Isthmian Canal Zone, served as a physician to the Isthmian Canal Commission from July 17, 1909 to April 6, 1913, served on the Costa Rica Panama Boundary Commission, was medical director and chief surgeon for the Standard Oil Company, aged 58, died, June 20, in Chapel Hill, N C, of cerebral hemorrhage

Francis Gabriel Minter Ⓢ Boston, Tufts College Medical School, Boston, 1913, member of the American Academy of Ophthalmology and Oto-Laryngology and the New England Otolological and Laryngological Society, served during the World War, aged 53, on the staffs of the Cambridge (Mass) City Hospital, St Margaret's Hospital and the Carney Hospital, where he died, April 10, of pneumonia, following an operation for appendicitis

Victor Mildenberg, Jamaica, N Y, Long Island College Hospital, Brooklyn, 1898, member of the Medical Society of the State of New York, director of the bureau of preventable diseases of the New York City Department of Health, veteran of the Spanish-American War, member of the National Defense Council during the World War, on the staffs of the Jamaica and Mary Immaculate hospitals, aged 61, died, April 13

Sally Josephine McCollum, Chicago Illinois Medical College Chicago, 1898 Northwestern University Woman's Medical School, Chicago, 1899 member of the Illinois State Medical Society and the Associated Anesthetists of the United States and Canada, on the staff of the Women and Children's Hospital, aged 76 died April 24, of arteriosclerosis diabetes mellitus and lobar pneumonia

Daniel Charles O'Neil Ⓢ Binghamton, N Y University and Bellevue Hospital Medical College New York 1899 served during the World War at one time medical superintendent of the Endicott Johnson Clinton Street Hospital, aged

59, on the staff of the Charles S Wilson Memorial Hospital, Johnson City, where he died, April 22 of coronary occlusion

Clifford Joseph Ouellette Ⓢ Oconto Wis Marquette University School of Medicine Milwaukee 1914, served during the World War, county physician for a number of years past president and secretary of the Oconto County Medical Society, on the staff of the Oconto City and County Hospital, aged 47 died, April 29, in a hospital at Milwaukee

J Baldwin McComb, Palo Alto, Calif, Starling Medical College, Columbus, 1897, formerly connected with the U S Public Health Service for many years on the staff of the U S Veterans Administration, stationed at Alexandria and Algiers aged 63, died, April 21, of tumor of the meninges and coronary occlusion

William Connely McDonough Ⓢ Topeka, Kan, Rush Medical College, Chicago 1902 member of the Radiological Society of North America, at one time demonstrator of anatomy at the Kansas Medical College on the staffs of St Francis Hospital and the Christ Hospital, aged 69 died, April 17 of chronic myocarditis

Harry Hartzell Penrod Ⓢ Johnstown Pa Jefferson Medical College of Philadelphia, 1904 served during the World War, past president of the Cambria County Medical Society, aged 61 formerly on the staff of the Conemaugh Valley Memorial Hospital, where he died, April 7, of chronic nephritis and myocarditis

William John Middleton, Steelton, Pa, Jefferson Medical College of Philadelphia, 1879, member of the Medical Society of the State of Pennsylvania, past president of the Dauphin County Medical Society and the Harrisburg Academy of Medicine, aged 79, died, April 13, in Atlantic City, N J, of coronary sclerosis

Everett Edwin Robinson Sr, Meridian, Miss, University of Nashville (Tenn) Medical Department, 1902, member of the Mississippi State Medical Association, at one time professor of minor surgery and assistant to the chair of gynecology at the Mississippi Medical College, aged 60 died, April 4

John Roberts, Kingston, Tenn Tennessee Medical College, Knoxville, 1898 member of the Tennessee State Medical Association chairman of the county board of education formerly county health officer, aged 67, died, April 29, of myocarditis and arteriosclerosis

Edward N B Mershon, Saxonburg Pa, University of Buffalo School of Medicine, 1877, member of the Medical Society of the State of Pennsylvania, also a pharmacist, for many years president of the school board and board of health, aged 88, died, April 23

John Kimball Parish Ⓢ Hermansville, Mich Tulane University of Louisiana School of Medicine New Orleans 1919 secretary of the Menominee County Medical Society on the staff of the Pinecrest Sanatorium, Powers aged 40 died, April 18, of pneumonia

Sylvan Myers, Vicksburg, Miss, University of Pennsylvania Department of Medicine, Philadelphia, 1894, at one time county health officer, formerly on the staff of the Mississippi State Charity Hospital, aged 63, died suddenly, April 30, of coronary thrombosis

James John Meece, Dunmore Pa, Jefferson Medical College of Philadelphia 1928, member of the Medical Society of the State of Pennsylvania, county jail physician aged 34 died, April 10, in the Mercy Hospital, Scranton of septicemia following furunculosis

Wayman C Melvin, Linden, N C, University College of Medicine, Richmond, Va, 1900, member of the Medical Society of the State of North Carolina, member of the school board, aged 61, died, April 26, in the Goodhope Hospital, Erwin, of pneumonia

William Edward Rudd, Salem Mo Barnes Medical College, St Louis, 1897, member of the Missouri State Medical Association, served during the World War aged 66 died, April 22, of coronary thrombosis, myocarditis and arteriosclerosis

William Edwin Savage, Lynchburg, Ohio, Medical College of Ohio, Cincinnati 1899, member of the Ohio State Medical Association, served during the World War, aged 65, died, April 21, in the Good Samaritan Hospital, of cerebral hemorrhage

Julius Jay Selman Ⓢ Cleveland, Western Reserve University School of Medicine Cleveland, 1917, on the staffs of the City Hospital and the Mount Sinai Hospital, aged 44, died, April 24, of injuries received when he fell from a ninth story window

William Edwards Shastid, Pittsfield, Ill., Jefferson Medical College of Philadelphia, 1886, member of the Illinois State Medical Society, formerly secretary of the Pike County Medical Society, aged 74, died, April 4, of cerebral hemorrhage

Clarence Charles McCreery @ Fall River, Mass., Long Island College Hospital, Brooklyn, 1911 fellow of the American College of Surgeons, orthopedic surgeon to the Truesdale Hospital, aged 47, died, April 23, of coronary thrombosis

Joseph T. Newlove, Minot, N. D., Detroit College of Medicine, 1896, member of the North Dakota State Medical Association, on the staffs of the Trinity Hospital and St. Joseph's Hospital, aged 69, died, April 16

James E. O'Connell, Milwaukee, Wisconsin College of Physicians and Surgeons, Milwaukee 1905, aged 71 died April 6, in the Milwaukee General Hospital, of carcinoma of the stomach and sigmoid

John David McRae @ Chippewa Falls, Wis., McGill University Faculty of Medicine, Montreal, Que., Canada, 1897, on the staff of St. Joseph's Hospital, aged 68, died suddenly April 21, of lobar pneumonia

James R. Linzy, North Little Rock, Ark., Memphis (Tenn.) Hospital Medical College, 1897, aged 68, died, April 15, in the Baptist State Hospital, Little Rock, of chronic myocarditis and nephritis

Herbert M. McConathy, Tampa, Fla., University of Louisville (Ky.) Medical Department, 1898, veteran of the Spanish-American War, aged 67, died suddenly, April 1, of chronic myocarditis

Frederick Lucius Muth, Wilmerding, Pa., Hahnemann Medical College and Hospital of Philadelphia 1898, president of the board of health of Wilmerding, aged 60, died, April 20, of lobar pneumonia

George Washington Johnson, San Antonio, Texas, Eclectic Medical Institute, Cincinnati, 1883, member of the State Medical Association of Texas, aged 76, died, April 5 of bronchopneumonia

Oscar A. Lambert, Okmulgee, Okla., Starling Medical College, Columbus, 1894, at one time mayor of Marietta, Ohio, aged 71, died, April 23, in Lakeland, Fla., of acute dilatation of the stomach

Nathan Smilie, Philadelphia, Hahnemann Medical College and Hospital of Philadelphia 1894, aged 68, died, April 27, in the Jackson Memorial Hospital, Miami, Fla., of cerebral hemorrhage

Vera Mae Irene McDorman, Moose Jaw, Sask., Canada, University of Manitoba Faculty of Medicine, Winnipeg, 1932, house physician to the Providence Hospital, aged 28, died, March 12

James W. Pinch, Milwaukee, Michigan College of Medicine and Surgery, Detroit, 1891, aged 72, died, April 30, in the Evangelical Deaconess Hospital of chronic myocarditis

John J. Raaf @ Pocatello, Idaho, Barnes Medical College St. Louis, 1898, on the staffs of the Pocatello General Hospital and St. Anthony Mercy Hospital, aged 65, died April 9

Eugene S. Miller, Childersburg, Ala. (licensed in Alabama in 1908), formerly health officer of Macon County, aged 54, died, April 26, in a hospital at Sylacauga, of pneumonia

Arthur Ross Mead, Jeffersonville, Ind., University of Louisville (Ky.) Medical Department 1911, aged 50, died, April 11, of influenza and hypertensive heart disease

George Frederick Seitters, Liberty, Ohio, Eclectic Medical College, Cincinnati 1919, aged 61, died April 6, in the Miami Valley Hospital, Dayton, of lobar pneumonia

John Bunyon Johns, Bethany, La., University of Louisville (Ky.) Medical Department, 1890, aged 72, died, April 10, in a hospital at Texarkana, Ark., of chronic malaria

Louis Winfield Myers, Los Angeles, College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1905, aged 55, died, April 3

Edward Clay Robinson, Augusta, Ga., Leonard Medical School, Raleigh, N. C., 1901, aged 61, died, April 10, of hemiplegia, cerebral hemorrhage and hypertension

Horace R. Rankin, Chicago, University of Louisville (Ky.) Medical Department, 1897, aged 67, died, April 11, in the Cook County Hospital of pulmonary tuberculosis

Preston Allan Miller Lyster, Chula Vista, Calif., McGill University Faculty of Medicine, Montreal, Que., Canada, 1922, aged 47, died, April 26, of coronary thrombosis

Hagop H. Rejebian, New York, Bellevue Hospital Medical College New York, 1888, member of the Medical Society of the State of New York, aged 71, died, April 3

James Monroe Sample, New Washington, Ind., Louisville (Ky.) Medical College, 1907, aged 55, died, April 25, in Madison, of sclerosis of the spinal cord

Charles D. McKenzie, Cincinnati, Cincinnati College of Medicine and Surgery, 1896, aged 81, died, April 3, in St. Francis Hospital, of arteriosclerosis

A. L. Norfleet, New York, St. Louis Medical College 1881, aged 79, died, April 24, in the Columbia Presbyterian Medical Center, of cirrhosis of the liver

John W. Linthicum, Catonsville, Md., University of Maryland School of Medicine, Baltimore, 1884, aged 75, died, April 18, of nephritis and heart disease

Alfred Mitchell Butterfield, North Troy, Vt., University of Vermont College of Medicine, Burlington, 1905, aged 55, died, April 25, of epithelioma

Samuel Harvey McCoy, Ottawa, Ont., Canada, University of Toronto Faculty of Medicine 1892, F.R.C.S., of Edinburgh, Scotland, 1905, aged 71, died, April 9

Charles W. McFarling, Tulsa, Texas, University of Tennessee Medical Department, Nashville, 1901, aged 64, died April 3, of influenza and pneumonia

Marion Edmond, Eagle Rock, Va., Medical College of Virginia, Richmond, 1901, member of the Medical Society of Virginia, aged 59, died, April 25

Emma Comly Waln Goodman, Ambler, Pa., Woman's Medical College of Pennsylvania, Philadelphia, 1893, aged 80, drowned in a bathtub, April 26

Carrie Estella Slaght, Interlaken, N. Y., Rush Medical College, Chicago, 1915, aged 52, died, April 1, of fibroids of the uterus and acute nephritis

James Alexander McNaughton, Los Angeles, University of Toronto Faculty of Medicine, 1893, served during the World War, aged 67, died, April 28

Harry Alexander Manchester @ Lincoln, R. I., Long Island College Hospital, Brooklyn, 1899, aged 59, died in April of cerebral hemorrhage

Charles James Fox, Pubnico, N. S., Canada, University of Pennsylvania Department of Medicine, Philadelphia, 1876, aged 86, died, March 24

Francis Edward Croghan, Providence, R. I., Georgetown University School of Medicine, Washington, D. C., 1908, aged 54, died, April 29

Ignatz Lange, Chicago, Rush Medical College, Chicago, 1888, aged 75, died, April 27, in the Columbus Hospital, of ruptured duodenal ulcer

Henry B. Rue, Hoboken, N. J., University of Pennsylvania Department of Medicine, Philadelphia, 1880, aged 81, died, April 2, of myocarditis

Henry Medd, Philadelphia, Jefferson Medical College of Philadelphia, 1896, also a druggist, aged 78, died, April 16, of cerebral hemorrhage

Guy Stewart Peppers, Fort Pierce, Fla., Baltimore Medical College 1911, served during the World War, aged 56, died, April 20

James Scott St. Clair, Bonsack, Va., University of Virginia Department of Medicine, Charlottesville, 1880, aged 79, died, April 5

Edward Bryant Milburn, Calico Rock, Ark. (licensed in Arkansas in 1903), aged 63, died, April 10, of acute dilatation of the heart

Paul William Newcomer, Pomona, Calif., Denver and Gross College of Medicine, 1906, aged 62, died, April 20, of leukemia

Friedrich Wilhelm Schnauss, Jacksonville, Fla., Atlanta College of Physicians and Surgeons, 1906, aged 68, died, April 20

John H. Sayrs, Zion, Ill., Medical College of Ohio, Cincinnati 1884, aged 79, died suddenly, April 12, of angina pectoris

John Earl McCreery, Beckley, W. Va., University of the South Medical Department, Sewanee, Tenn., 1904, died, April 19

Henry Grundy, Toronto, Ont., Canada, University of Toronto Faculty of Medicine, 1890, aged 77, died, April 8

John Barnett Mitchell, San Francisco, California, Medical College San Francisco, 1895, aged 76, died, April 11

Robert William Rooney, Orangeville, Ont., Canada, Trinity Medical College, Toronto, 1889, died, April 2

John Charles Reeve, Monterey, Calif., Jefferson Medical College of Philadelphia, 1886, aged 77, died, April 8

Bureau of Investigation

DIABETES FRAUD EXPOSED

Brazen Scheme Conducted by Carr Laboratories and Martin Carr Barred from Mails

The Postmaster General, under date of June 22, 1937, closed the United States mails to the Carr Laboratories and Martin Carr of Spokane, Wash. Carr conducted one of the rankest of frauds in the mail-order diabetes field. Martin Carr and the Carr Laboratories were in a class by themselves when it came to brazenness in exploiting the diabetic.

According to the post office fraud order, the Carr Laboratories, a Washington corporation, was chartered Feb. 4, 1926, with 99,999 shares of stock of no par value, of which 33,000 shares are held by Martin Carr, president, 12,000 by G. A. Nikotich, vice president, 10,000 by Peter S. Pope, treasurer, and 10,000 by George Clair, secretary. The remainder of the stock is held in the treasury of the concern.

According to the statements of a Mrs. Elsie A. Merrick, who appeared for and in behalf of the concern at the hearing, Mr. Carr is a Czechoslovakian immigrant who "can't explain himself in this language." Mrs. Merrick was only vaguely informed as to Mr. Carr's educational background. According to the evidence, President Carr is engaged at present as a cook in an establishment called the "Little Brick Cafe." The Carr Laboratories are conducted by Mrs. Merrick, who is the wife of a half-brother of Secretary Clair. Although Mrs. Merrick is wholly without a medical education, she handled all mail and answered all questions asked by diabetic sufferers who corresponded with the Carr Laboratories.

CARR TREATMENT

ORDER THROUGH YOUR DRUGGIST

Carr Treatment is obtainable only through reputable druggists by direct order.

Carr Treatment is packed in bottles—each bottle containing sufficient Carr Treatment for one week's treatment. We recommend however, the purchase of four bottles at once, as the price of the Carr Treatment is usually expedient.

One Bottle Carr Treatment \$2.50
Four Bottle Carr Treatment \$9.00

CARR LABORATORIES
736 E. SPokane Ave.
Spokane, Washington

According to a booklet put out in 1926 by Carr's Diabetic Remedy Company, "Carr's Diabetic Treatment for Sugar in the Blood and Urine—A New Discovery" was "Offered to the Public for the First Time Feb. 15, 1926." As is frequently the case in "patent medicine" exploitation, the "remedy" was an old family possession, having come into the hands of Thomas Carr, Martin Carr's grandfather, "a country physician of Crkvenica, Austria-Hungary (now Jugo Slavia)" from "a prominent physician of Vienna." On the death of Thomas Carr, Martin Carr came into ownership of the formula. "Interested in this formula, Martin Carr prepared some of the medicine according to its directions. To do so required the purchasing of many ingredients and their slow and careful compounding over a period of many days."

The booklet calls attention to the fact that "Carr's Remedy is still compounded in this slow and painstaking manner under the personal supervision of Martin Carr." The legend does not state just when Martin Carr, cook at the "Little Brick Cafe," took off his apron and chef's cap and laid aside his short-order pans and skillets to become President Carr, the "painstaking" compounder of "Carr's Diabetic Remedy."

According to another booklet, "The first persons treated with Carr's Treatment were persons living in and about Spokane, Washington. Martin Carr personally supervised these treatments, calling on the patients four times daily to administer the medicine. News of the results spread until Mr. Carr could no longer possibly call on all the patients to administer his remedy." Which is quite understandable, as poor Mr. Carr must have been in a terrible dilemma trying to turn out a pot of Hungarian goulash with French fries at the "Little Brick Cafe," hurrying to Carr Laboratories to mix a batch of Carr's Diabetic Remedy, and then trying to find time to administer the concoction personally in teaspoon doses.

With unsurpassed brazenness the Carr Laboratories advertised the Carr treatment for diabetes in national publications. One of these advertisements reads as follows:

"DIABETICS

I would like to receive names and addresses of persons suffering from diabetes. I feel that I owe it to them to give the evidence accumulated by nine years experience. I will send you my valuable, interesting booklet FREE. It costs you nothing—no obligation. Send your name and address, that's all.

MARTIN CARR, President
CARR LABORATORIES, Dept. A,
P. O. Box 1964, SPOKANE, WASH."

Victims of the fraud, responding to the foregoing and similar advertisements, were forwarded a quantity of circular matter, one follow-up letter reading in part:

"Dear Friend—You wish to be well and strong again—to enjoy the blessing of perfect health. We can make your wish come true.

Carr's Diabetic Treatment is long past the experimental stage. Letters pour in to us from persons who have had complete recovery. 'My doctors had given me up.' 'I was pronounced incurable.' We would like to take you to visit persons it has cured completely—persons who have given us sworn affidavits to that effect.

The formula was submitted to the United States pure food authorities and approved by them as harmless and non-habit forming. Carr's Treatment means hope for you. Every statement I make to you in this letter or in our booklet is absolute truth.

According to the post office report, the formula used in manufacturing the liquid included in the Carr "treatment" is as follows:

Jumper berries	180 grains
Spanish saffron	420 grains
Quassia chips	10 grains
White agaric	420 grains
Oil of hemlock	4 ounces
Camphor	10 grains
Zedoary	420 grains
Rhubarb	420 grains
Venice	10 grains
Aloes	78 grains
Alcohol and water in equal parts to make a gallon	

Uncontroverted expert medical testimony adduced at the hearing showed that the Carr liquid is merely diuretic and laxative in effect, and wholly without therapeutic value in the treatment of diabetes. The dietary instructions furnished patrons, while held to be "moderately satisfactory for persons suffering from the disease in a mild form might prove not only useless but definitely harmful to individuals having severe cases thereof." The expert testimony also showed "that in many cases of diabetes the use of insulin is not only advisable but absolutely essential, and that dependence upon the Carr treatment in such cases will result inevitably in progressive loss of weight and strength, coma and death."

The claims in the Carr literature to the effect that the enterprise had been passed on favorably by the United States Food and Drug Administration had been continued despite the issuance of an order by the Food and Drug Administration directing withdrawal of similar statements from the labels and packages containing the "medicine."

The issuance of the post office fraud order removes from the mails, at least, a vicious scheme to lull the unfortunate person with diabetes into a false sense of security.

Correspondence

MICROSCOPIC REPRESENTATION OF THE SURFACES OF LIVING ORGANS

To the Editor—In THE JOURNAL, June 12, the Vienna correspondent reports on "Microscopic Representation of the Surfaces of Living Organs" and writes (p. 2054) "Thus far, however, enlargements up to a magnification of only about 30 diameters have been practicable for the observation of surfaces, and the instruments did not permit inspection of individual cells or their constituents. Dr. Pick, who holds the chair of anatomy at Vienna, devised a new apparatus by means of [which] he is able to obtain magnifications of 800 diameters."

Knowing from personal experience of the high standard with which you conduct THE JOURNAL and also of the exactness for which you are striving in your reports, I wish to call to your attention the misrepresentations in the sentences quoted. A decade ago three instruments were devised, one by Vonwiller, one by me, and one by Ellinger and Hirt, to suit various needs in observation of living tissues *in situ*. Magnifications of 800 and higher diameters were obtained and exact cytologic observations were made. Linear magnifications can be obtained by various means and as such do not have any value if the resolving power of the objective is not high. I devised objectives with 60 \times and 90 \times magnifications with a numerical aperture 0.8 and 0.9 and with comparatively long working distances. According to the eye pieces selected a magnification of 1,080 diameters can be obtained without blurring the image. The average magnification we use is 600 \times . Experiments similar to those described in the article of your correspondent were conducted in my laboratory by my co-workers and myself on a much broader scale, including observations of pathologic phenomena in fluorescence light as well as in white light. Reprints of my works relating to this subject are in your possession, as you had requested them for an editorial review at the time, when I had the pleasure of speaking to you in Chicago.

Dr. Pick's position is also not as stated. He does not hold the chair and I hope that Dr. Pick, whom I know by corresponding, will not suffer innocently by this erroneous report.

EDWARD SINGER, M.D., New York

TETANY OF THE NEW-BORN

To the Editor—Tetany in the new-born has received considerable attention in the recent literature. Some older physicians rather doubted its occurrence except as a clinical curiosity. Recent reports, however, indicate that the incidence of this disorder is on the increase. Why?

My interest was aroused in this subject by the occurrence of a dozen cases of convulsions of the new-born in a St. Louis hospital. I examined only one of these infants. In addition to a syndrome characteristic of tetany, edema was also present, and some of the symptoms clearly indicated an increase in the intracranial pressure. It was difficult to exclude the possibility of a late intracranial hemorrhage, and yet the infant completely recovered under the administration of calcium and a change in diet. In this hospital prelacteal feeding was freely

used as a routine. The mixture contained lactose 5 per cent and sodium citrate 1 per cent. We concluded that the large number of cases of tetany was produced by the alkalis in the food. The percentage of sodium citrate prescribed was 0.5 per cent, but through some technical error the infants received a 1 per cent solution. In another hospital where the lactose citrate (0.5 per cent) solution was used, no case of tetany occurred, but the infants received only a small quantity of the solution on the second day of life.

It is unfortunate that physicians reporting the cases in the recent literature have not given in detail the diet of the infant in the first few days after birth. I want to raise the question, is the increased incidence of tetany in some way connected with prelacteal feeding? In this hospital only well-to-do mothers under the private care of competent obstetricians are received. A deficiency in the diet of the mother scarcely merits consideration. In another hospital, in which a poorer class of mothers receive obstetric care and in which no prelacteal feeding had been instituted, not a single case of tetany was observed during the same period.

From this observation I am inclined to adopt the theory of Shannon that alkalosis is the chief metabolic disturbance causing tetany of the new-born.

For the present we have discontinued prelacteal feeding in the hospital, and no case of tetany has been observed in the last few months.

JOHN ZAHORSKY, M.D., St. Louis

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

DERMATITIS BETWEEN FINGERS

To the Editor—A white man, aged 42, married, who has two children has had no serious illnesses except a history of headaches with nausea and vomiting, and at times a good deal of dizziness. This condition occurred several years ago but has not bothered recently. In May 1936 while on a fishing trip a rash developed between the fingers on both hands. This looked like a poison ivy or poison oak and he treated it accordingly without consulting a physician. The lesions disappeared but since that time he has had repeated outbreaks. The lesions are typically like those of poison ivy or poison oak, with characteristic elevated blisters. They occur only between the fingers and occasionally extend a slight way on the palmar surface of the fingers and hands. They are not particularly uncomfortable except that he is conscious of it. The patient's physical examination is negative. The Wassermann and Kahn reactions are negative. The urine is normal. Microscopic examinations of scrapings of the skin show no mycelium or fungus like bodies, and scratch tests for foods and bacteria were all negative. Careful questioning as to contact with cosmetics or irritants of any kind (hair dyes, chemicals) have been negative. The lesions usually respond to almost any form of treatment used for a dermatitis venenata. I was wondering whether you could give me a suggestion as to what this condition might be and what treatment could be used to prevent recurrence.

WILLIAM J. MATOUSEF, M.D., Glendale, Calif.

ANSWER—Vesicular dermatitis in the webs of the finger along the sides of the fingers and on the palmar surfaces is very common and may be (1) ringworm infection, (2) dermatitis venenata, (3) eczema or (4) pompholyx.

1. Ringworm infection has not been ruled out in the case cited. It is not enough to examine scrapings. The tops of the vesicles should be removed, placed upside down on the slide and examined in from 10 to 50 per cent potassium hydroxide for spores and mycelia. The toes should be examined if no vesicles are present, macerated scales from between the toes may be used. Frequently, fungi can be found about the toes and not in preparations from the hands. This may mean that they are few in the hand lesions and therefore difficult to find, or it may mean that the hand lesions are dermatophytid, lesions in which the organisms have been destroyed by the resistant tissue.

The vesicles of ringworm infection are deep and do not break easily. There may be little redness or considerable. The lack of itching in the case under consideration and the ready subsidence of the eruption under soothing treatment have been

weight against the diagnosis of ringworm but do not rule it out. The presence of ringworm between the toes or on the soles would be strong evidence in favor of a trichophytid on the fingers.

If the diagnosis of ringworm is confirmed by direct examination of vesicles or scales from fingers or toes, treatment of the disease on the feet may prevent further recurrence of the hand eruption. The occasional use of Whitfield ointment, 5 per cent salicylic acid, 10 per cent benzoic acid in rose water ointment, on the feet, and 2 per cent salicylic acid with 4 per cent benzoic acid on the hands, may be effective in preventing recurrence.

2 and 3 The description given omits to mention the color of the eruption. Is it very red and do the thin vesicles break and form weeping areas? Judging from the lack of itching, 'they are not particularly uncomfortable,' it is not at all typical of dermatitis venenata or of eczema. It is difficult to imagine either of these behaving so benignly.

The opportunity for contact with irritants is so frequent that it is impossible to rule them out except by keeping the hands covered. Soap is the commonest offender. See the list of irritants given by L. F. Weber (*External Causes of Dermatitis*, *Arch. Dermat. & Syph.* 33:129 [Jan.] 1937). Scratch tests are of no value in testing for these diseases. Patch tests must be made, fastening the suspected substance on the unaltered skin, preferably on the arm or back, and leaving the patch for forty-eight hours.

4 Pompholyx or disidrosis is manifested by an eruption like that described. It used to be frequently diagnosed, but of late ringworm fungi have been found so often in cases of this kind that many have been come to believe that all such cases are caused by fungi. This may be the case, but there still remain some vesicular eruptions of the hands and feet in which fungi are not found. If there is such a disease as pompholyx, it is supposedly a sweat duct disorder caused by an intestinal toxin in persons whose resistance is reduced by nervousness, worry or overwork.

Soothing lotions or ointments locally and tonics or change of climate are recommended. The case in question, the lesions of which yield so readily to soothing applications, is possibly a pompholyx. The prevention of this is a problem which is far from solution. Maintenance of good health and building up of general resistance are first requisites. Use of salicylic acid, from 0.5 to 1 per cent in 50 per cent alcohol, as a lotion on the hands may help. Suberythema doses of ultraviolet rays, local and general, may aid. This should be tried out on a small area first to rule out the rather unlikely possibility that a sensitization to light exists.

HAY FEVER IN THE SOUTH

To the Editor—I have a wife and child who have severe hay fever. They are allergic to annual pea, walk grass, meadow fescue, beach grass, sweet vernal grass, wild oats, California brome grass, woodland brome grass, seaside brome grass, Bermuda grass, alkale rye grass, velvet grass, meadow barley, Australian rye grass, darnel, timothy, Johnson grass, cat epithelium, dog epithelium, duck feathers, goose feathers, kapok, mustard, western ragweed, white elder, hick, walnut, blue gum, caryate date palm, careless weed, rough pigweed, pepper tree, Monterey cypress, Italian cypress, silver acacia, ash, and Fremont poplar. The dust and dryness here seem to make them worse. I have had them listed by allergists here and in Los Angeles and San Francisco. As the government has hospitals in Gulfport, Miss., Augusta, Ga., and Lynchburg, Va., I was thinking of trying to obtain a transfer as we live in the South. How would these climates agree and what ones offer the best chance of help?

M D Arizona

ANSWER—An analysis of the positive skin reactions (not necessarily synonymous with hypersensitivity or allergy—a positive skin test may mean past, present or future trouble) reveals that sixteen of them are to various members of the grass family. Of these Bermuda grass is probably the most important cause of hay fever in the South and, as all the locations mentioned, including Tucson, are in the South, a change of location would probably not help.

We are assuming that Bermuda grass is the important factor, but as the time of symptoms is not mentioned in the query there is some doubt. As to the trees enumerated it would be best to see whether symptoms occur when these are pollinating. Trees pollinate for relatively short periods. The tree problem is a local one.

The reactions to careless weed, rough pigweed and ragweed may be important. Does the hay fever come late? Watson and Kibler in a pollen survey of Arizona and the Southwest (*THE JOURNAL*, March 11, 1922, p. 719) showed that early hay fever (February and March) is due chiefly to cottonwood and ash trees, and that the spring type is due chiefly to Bermuda grass (*Capriola dactylon*), which blooms throughout the spring, summer and autumn months and is the important cause at altitudes

up to 4,500 feet. At higher altitudes June grass (*Poa pratensis*) replaces Bermuda grass in importance during the spring. Also important in spring are rabbit bush (*Franseria deltoidea*), a ragweed, and shad scale (*Atriplex canescens*), a member of the goosefoot group.

The fall type is due chiefly to the pigweeds (*Amaranthus palmeri* and *Amaranthus retroflexus*), with false ragweed (*Franseria tenuifolia*) as a factor of secondary importance. The amarantids of the Southwest take the place of the ragweeds of the East and of the artemisias in the Rocky Mountain region. E. W. Phillips (*Southwest Med.* 7:273 [Aug.] 1923) made a similar survey with similar results.

It would seem wise to take injections with a view to hypodermatization from some physician familiar with the local flora. If this procedure should not be agreed to or if it has been tried and has failed, removal north or northeast would practically eliminate suffering from Bermuda grass and from the amarantids.

The positive tests to cat and dog hair and duck and goose feathers and to kapok may be associated with perennial symptoms. It would seem advisable to avoid these as much as possible.

EPILEPSY

To the Editor—A woman aged 41, a housekeeper who for the past year has been having nocturnal convulsions, has had attacks usually within one week of the menstrual period either preceding or following it. The convulsion is characteristic each time occurring while the patient is asleep and begins as a tonic contraction of all the muscles with the extensors predominating as the attack wears off the spasms become clonic, the neck being rigid, the pupils dilated and nonreactive. There is chewing of the tongue. The patient does not awaken following the attack but sleeps on until her usual hour for rising. She recalls nothing of the attack and experiences only soreness of the muscles of the neck following the attack. The blood pressure and pulse have been normal on two occasions when I have seen the patient during the convulsion. There are no prodromes and the patient has no warning of the impending attack. The history reveals only the following positive facts: The menstrual periods have been occurring about every twenty-five days since the onset. They had previously been regular and of the twenty-eight day variety. The patient began menstruating at 12 years of age. For the past seven years she has had an essential hypertension which responds to rest and sedation. The blood pressure range is from 130/90 to 180/110. There is no evidence of impairment of the kidney function or of arteriosclerosis. An older sister is now confined to an asylum with what I assume to be a manic depressive psychosis. A brother is also said to have been insane but I am unable to arrive at any conclusion as to the type from the history. Physical examination reveals three decayed and dead teeth and small cryptic infected tonsils which have been partially removed by the electric cautery. There is no other evident focus of infection. The neurologic examination is negative. There is no evidence of mental deterioration. During July, August and September, 1936, the patient was free from convulsions. During this period she had one dose of theelin (1,000 units) and was undergoing treatment of the tonsils (electric cautery). At present only a small amount of tonsillar tissue remains and all dental work has been done except for extraction of the dead tooth. From the foregoing can you give any hint as to diagnosis and proper treatment? Please omit name.

M D Tennessee

ANSWER—The diagnosis, based on the history of the attack as given, is epilepsy. The nocturnal character, the association with the menstrual period and the sequence of events are all in accord with this diagnosis. The cause of the disease, beginning at the age of 40, is suggested by the history of essential hypertension, a condition often leading to cerebral arterial changes, with hemorrhage and edema of brain tissue. This is often clearly depicted in the appearance of the optic fundi, in which choked disk and vascular disorder can be easily observed. Also important is the history of grave mental disease in the patient's family. Brain tumor, the most common cause of epilepsy after the age of 40, and neurosyphilis have not been ruled out by complete investigation. A check of the optic fundi, fields of vision, x-ray examination of the skull and lumbar puncture should all be done before the physicians rest secure in making a diagnosis so grave as epilepsy. It is only by such studies that we can be sure that we have not missed essential facts that would lead to a complete change in the treatment such as an operation for brain tumor or antisyphilitic treatment for neurosyphilis. Epilepsy is no longer a complete diagnosis; one must think in terms of the epilepsies. If evidence for brain tumor or neurosyphilis is not found the patient's disorder should be provisionally classified as one of nocturnal epilepsy of probably vascular origin. In this condition phenobarbital has proved to be a most valuable remedy, used in doses of from 0.03 to 0.1 Gm. doses at bedtime. Once a satisfactory dose is agreed on, this should be continued indefinitely and probably during the patient's entire life. A single physician over a long period, a single drug and continued observation for signs of important causative factors, which may not appear for some years, are often the secret of the care of the epileptic patient in private practice.

DOG TYPHUS OR STUTTGART DISEASE

To the Editor—I have been informed that there is a condition in dogs known as dog typhus. The symptoms of the disease in dogs appear to be almost like the typhus of man. Is it possible for man to contract this 'dog typhus'? My interest in this was aroused by a friend of mine who had several dogs die with dog typhus. Any information you may give will be appreciated by both of us. Please omit name.

M D, Kansas

ANSWER—Dog typhus is also known as Stuttgart disease. It has appeared periodically for years in England and continental Europe in epizootic form. In the course of the disease severe gastro-intestinal inflammation is observed, frequently complicated by ulcerative stomatitis and nervous symptoms.

This disease is closely allied to, and believed by some to be the same as, infectious jaundice, or Weil's disease, in man, which is caused by a spirochete, *Leptospira icterohaemorrhagiae*. This spirochete is believed also to be the cause of dog typhus. It has been found in the lungs, liver and kidneys of dogs dead of typhus. The disease does not seem to be transmitted from dog to dog by contact. The common rat appears to be the host of the leptospira. The disease is spread by dogs eating rats harboring the leptospira or by such rats soiling the food of dogs by their excretions.

During the past fifteen or twenty years the disease in dogs has been reported from various parts of this country, but because of lack of laboratory confirmation these have been doubted.

Recently Dr E. Jungheer of the Storrs Agricultural College at Storrs, Conn., has reported finding spirochetes resembling morphologically *Leptospira icterohaemorrhagiae* in the lungs, liver and kidneys of three dogs dead of a disease in which the necropsy disclosed conditions the same as those of the European disease. These cases appear to be the first reported in this country which are supported by laboratory evidence.

DEFINITION IN PSYCHIATRY

To the Editor—Having found the information from the usual sources confusing, incomplete or contradictory, I should like the accepted as accurate as possible definitions and the distinctions between the following words: (1) neurosis (2) anxiety neurosis (3) compulsion neurosis (4) psychasthenia (5) psychoneurosis (6) neurasthenia and (7) hysteria. Also please either state or give reference to the exact definition and the exact technique (naturally there are many so the most commonly used method) of (1) psychoanalysis and (2) hypnosis. It is astounding that despite the realization of its importance and continual reference to it, psychotherapy almost always is dismissed by mere mention or is hidden in a morass of semimystical terminology.

MICHAEL B. SHINKIN M.D. San Francisco

ANSWER—These questions require answers so extensive and embodying so much controversial material that it is recommended that the standard works of psychopathology be consulted. Among these Henry's Psychopathology, Malamud's Psychopathology, Diethelm's Treatment in Psychiatry and Hart's Psychology of Insanity may be profitably perused. The usage of the words included in the question varies considerably with the so-called schools of psychiatry. Psychotherapy, meaning literally psychologic treatment, is a broad term covering many techniques, but so does physical therapy.

PUTTEES AND BUERGER'S DISEASE

To the Editor—I am finding a number of cases of Buerger's disease in retired army officers. I wonder if this could be caused by the long use of puttees. They must more or less restrict circulation. This is one question I should like to have published in THE JOURNAL to see what reaction we can get from the experience of other men.

M D Florida

ANSWER—In recent years there has been a tendency to use the diagnosis of thrombo-angitis obliterans, or Buerger's disease, rather indiscriminately. Usually it causes obliteration of the arteries of the extremities of persons less than 45 years of age, who are almost uniformly excessive smokers of tobacco and who are predominately Jewish, although the disease has been described as affecting persons of almost all nationalities. Superficial phlebitis occurs at some time during the course of the disease in about 40 per cent of the cases. There is no consistent history of the use of puttees, in fact in a large series of cases the number of army officers has been conspicuously small.

Since the correspondent speaks of retired army officers it seems permissible to assume that they are in the later decades of life and that if they have chronic occlusive arterial lesions these are much more apt to be degenerative than inflammatory, that is, the diagnosis is more apt to be arteriosclerosis obliterans

than thrombo-angitis obliterans. Before one can answer the correspondent's question, one would need to know whether or not the incidence of this type of arterial lesion is more frequent in army officers than in a group of persons of comparable age who have not worn puttees. It is not apparent that the use of puttees ordinarily obstructs the arterial circulation, although it may cause compression of the superficial veins. However, it is difficult to understand how such compression could produce organic changes in the arteries. The opinion is that the use of puttees does not cause occlusive arterial lesions, although this is not a certainty.

SENSITIVITY TO ARSPHENAMINE IN SYPHILIS

To the Editor—A white woman aged 28 developed a chancre on the eyelid six months ago. This lesion was allowed to go untreated until a Wassermann reaction was four plus at which time treatment was started. After five doses of neoarsphenamine she developed an arsenical dermatitis. The arsenic was left off and bismuth therapy instituted in conjunction with mixed treatment by mouth. All of this transpired prior to my seeing her. I should like to ask your advice as to what treatment she should receive from now on. She had had weekly injections of a bismuth compound before coming under my care. If you will kindly outline the treatment I should follow with her I shall be obliged. M D Georgia

ANSWER—The history of an arsenical dermatitis following five doses of neoarsphenamine warrants the use of considerable caution in the further treatment of this patient. A woman of 28 with acute syphilis is in need of special effort to arrest the disease because of the eventuality of a pregnancy and an infected offspring. If the dermatitis was a generalized exfoliative one of severe degree, sufficient time has not as yet elapsed to try her again on one of the arsphenamines. If, however, the dermatitis was mild and disappeared in a few days, it might be that she would now tolerate one of the other arsenic preparations, such as mapharsen. The dose, however, should be a minimal one, starting, for example, with 0.005 Gm and increasing the dose 0.005 Gm with each injection up to but of course not exceeding the full dose of from 0.03 to 0.04 Gm, if this is tolerated by the patient. If she shows evidence of intolerance to the mapharsen the subsequent treatment must be limited to preparations of bismuth or mercury. The bismuth compound should be given continuously, every five or seven days for at least eighteen months. The spinal fluid reaction should be determined, especially if the blood reaction remains positive.

COLON BACILLI AND KETOGENIC DIET

To the Editor—Will you please inform me which variety or varieties of colon bacilli respond best to ketogenic diet therapy? Does the same apply to mandelic acid therapy? Please omit name. M D Florida

ANSWER—Beta-oxylbutyric acid and mandelic acid are similar in that their bactericidal actions are developed at a concentration below 1 per cent and at a pH of 5.5 and below, as shown by both in vitro experiments and clinical trial. The gram negative bacilli that are most easily killed off by means of the ketogenic diet or the administration of mandelic acid are those of the subgroup *Escherichia coli* (*Bacillus coli*). Aerobacter aerogenes (*Bacillus lactis-aerogenes*) varies in its response, some corresponding closely to *Escherichia coli* and others being killed off with greater difficulty. The same applies to *Pseudomonas aeruginosa* (*pyocyaneus*). The *Proteus* organism in in vitro experiments is killed off just as readily as in *Escherichia coli*, but owing to the fact that it produces a very strongly ammoniacal urine it is difficult to make the urine sufficiently acid to obtain bactericidal action.

BRAIN INJURY AND BLOOD SUGAR

To the Editor—I should like some information concerning the relationship of brain injury to the blood sugar. Given a diabetic patient whose blood sugar was 166 mg per hundred cubic centimeters of blood some two weeks prior to an accident in which he received a brain injury and died. The blood sugar taken several hours before the patient died was 250 mg per hundred cubic centimeters of blood. I should like to know what extent if any the injury had on the increase of blood sugar.

A C BAIRD M.D. Parsons A N

ANSWER—Claude Bernard in 1855 was the first to demonstrate the relationship of the brain to carbohydrate metabolism. He punctured the region of the floor of the fourth ventricle in animals and found that they developed a prolonged glycosuria. In such experimental animals the blood sugar often attains very high values.

Lesions in the hypothalamic region may cause hyperglycemia. Stimulation of the thoracic autonomic center in the hypothalamus as well as irritation of the pons and medulla (Donhofier

and Macleod) cause hyperglycemia. Thus lesions of the brain involving the pathways which carry glycogenolytic impulses to the liver, or the tracts which supply the adrenals, pancreas or pituitary, may cause serious disturbances of carbohydrate metabolism. Any interference with the activity of the respiratory center may produce hyperglycemia by causing asphyxia.

Severe nervous or mental shock following injuries, or severe emotional disturbances, not infrequently precede the onset of diabetes mellitus. Various injuries and diseases of the central nervous system, such as concussions, skull fractures, apoplexies or brain tumors, may produce hyperglycemia or aggravate an existing diabetes.

It must not be forgotten that infection with acidosis, dietary indiscretions, hyperthyroidism, hyperpituitarism and renal disease are frequent causes of the rise in blood sugar.

CHRONIC CYSTIC MASTITIS

To the Editor—A woman aged 41, has been lactating from the left breast since the birth of a boy eight years ago. The right breast is normal. Three pregnancies were ended with curettements previously because of pernicious vomiting otherwise the past history is negative. She has various neuritic pains on the left side which radiate to the left shoulder and even to the back. To the touch the left breast feels larger, no masses are present. The patient does have some sort of endocrine unbalance. I believe. What will stop the breast from forming milk? Please omit name. M D Arkansas

ANSWER—The condition seems to be a chronic cystic mastitis, characterized by localization in one breast and radiating pain. It probably originated during the last pregnancy or the interrupted pregnancies could have influenced the condition. If the endocrines were a factor in this case at present, both breasts should be involved.

The fluid coming from the breast probably is not milk but is a secretion of the glands as a result of irritation or subacute inflammation.

The condition of the breast should be observed from time to time, for there is always the possibility of a malignant condition developing, although this is not of frequent occurrence.

DRUGS ANTAGONISTIC TO EPINEPHRINE

To the Editor—I am inquiring about an antidote in case of an accidental injection of epinephrine during a local infiltration of procaine hydrochloride. On two occasions I have injected a little epinephrine possibly intravenously followed rapidly by symptoms which are very severe headache feeling as if the top of the head were coming off and flushing which are a little embarrassing to the operator when he has told the patient that the injection would be relatively symptomless. I wonder what you have to suggest as to an antidote. Would one of the choline derivatives be of any use in counteracting the effect of the epinephrine? I will appreciate any assistance you have to offer.

JOHN W. COOPER, M.D. Honolulu T. H.

ANSWER—Nitrite antagonizes the vasoconstriction due to epinephrine and the cautious inhalation of amyl nitrite might be tried. Histamine may be of value.

DIABETES AND WEATHER

To the Editor—A diabetic patient whose blood and urine are free from sugar in a cold climate is quite diabetic in warm weather. Short wave diathermy causes sugar to appear in the urine without change in the diet or the administration of insulin.

LOUIS L. SHERMAN, M.D. Oakland Calif.

ANSWER—A moderate increase in the amount of insulin required has been observed frequently in warm weather. One possible explanation is the loss of salt (sodium) by perspiration. McQuarrie's observations indicate that the amount of insulin required is to some extent dependent on the supply of sodium (Thompson, W. H. and McQuarrie, I. *Proc Soc Exper Biol & Med* 31:907 [May] 1934. Glass, J., and Beiliss, I. *Ztschr f d ges exper Med* 73:801, 1930).

BJERRUM'S SCOTOMA

To the Editor—I would appreciate any information you can give me on the radius of curvature of Bjerrum's scotoma. Please omit name. M D, New York

ANSWER—This question is not clear. The radius of curvature of the scotoma varies according to the size and length of time that it has been in existence. In the beginning, the Bjerrum scotoma in glaucoma starts from the inner edge of the blind spot and hence has a radius of curvature of about 135 degrees.

Medical Examinations and Licensure

COMING EXAMINATIONS

STATE AND TERRITORIAL BOARDS

Examinations of state and territorial boards were published in *The Journal* July 10, page 156.

NATIONAL BOARD OF MEDICAL EXAMINERS

NATIONAL BOARD OF MEDICAL EXAMINERS *Parts I and II* Sept 13-15. Ex. Sec. Mr. Everett S. Elwood, 225 S. 15th St. Philadelphia.

SPECIAL BOARDS

AMERICAN BOARD OF INTERNAL MEDICINE. *Written examination* will be held in different centers of the United States and Canada Oct. 18. Chairman, Dr. Walter L. Biering, 406 Sixth Ave. Rm. 1210, Des Moines, Iowa.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY. *Group B Written examination* will be held at various cities throughout the United States and Canada Nov. 6. *Case histories must be submitted at this time.* Sec. Dr. Paul Titus, 1015 Highland Bldg. Pittsburgh (6).

AMERICAN BOARD OF OPHTHALMOLOGY. Chicago Oct. 9. *All applications and case reports, in duplicate, must be filed at least sixty days before the date of examination.* Sec. Dr. John Green, 3720 Washington Blvd. St. Louis Mo.

AMERICAN BOARD OF ORTHOPAEDIC SURGERY. Los Angeles Jan. 14-15. Sec. Dr. Fremont A. Chandler, 6 N. Michigan Ave. Chicago.

AMERICAN BOARD OF OTOLARYNGOLOGY. Chicago Oct. 8-9. Sec. Dr. W. P. Wherry, 1500 Medical Arts Bldg. Omaha.

AMERICAN BOARD OF PEDIATRICS. Los Angeles Nov. 14. Sec. Dr. C. A. Aldrich, 723 Elm St. Winnetka Ill.

AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY. New York Dec. 28 (tentative). Sec. Dr. Walter Freeman, 1028 Connecticut Ave. N.W. Washington D. C.

AMERICAN BOARD OF RADIOLOGY. Chicago Sept. 9-11. Sec. Dr. Byrl R. Kirklin, 102-110 Second Ave. S.W. Rochester Minn.

AMERICAN BOARD OF SURGERY. *Part I (written)* Sept. 20. Sec. Dr. J. Stewart Rodman, 225 S. 15th St. Philadelphia.

Colorado April Report

Dr. Harvey W. Snyder, secretary, Colorado State Board of Medical Examiners, reports the written examination held in Denver, April 7-9, 1937. The examination covered 8 subjects and included 165 questions. An average of 75 per cent was required to pass. Four candidates were examined, all of whom passed. Nine physicians were licensed by endorsement. The following schools were represented:

School	PASSED	Year Grad	Per Cent
Kaiser Wilhelms Universität Strassburg Osteopaths †	Medizinische Fakultät (1907)	75	79.5*
School	LICENSED BY ENDORSEMENT	Year Grad of	Endorsement
University of Arkansas (1932) Missouri	School of Medicine	(1926)	Arkansas
Rush Medical College		(1914)	Illinois
University of Illinois College of Medicine		(1928)	Illinois
University of Louisville School of Medicine		(1927)	Kentucky
Harvard University Medical School		(1932) N. B. M. Ex.	
University Medical College of Kansas City	Missouri	(1913)	Nebraska
Jefferson Medical College of Philadelphia		(1905)	Illinois
Vanderbilt University School of Medicine		(1899)	Wyoming

* Verification of graduation in process.

† Licensed to practice medicine and surgery.

Hawaii April Examination

Dr. James A. Morgan, secretary, Board of Medical Examiners, reports the oral and written examination held in Honolulu, April 12-15, 1937. The examination covered 10 subjects and included 80 questions. An average of 75 per cent was required to pass. Six candidates were examined, five of whom passed and one failed. The following schools were represented:

School	PASSED	Year Grad	Per Cent
Chicago College of Medicine and Surgery		(1916)	85.4
Chicago Medical School		(1920)	75
Loyola University School of Medicine		(1934)	78.7
University of Michigan Medical School	(1923) 80.5	(1934)	83.2

School	FAILED	Year Grad
Licentiate of the Royal College of Physicians of London and Member of the Royal College of Surgeons of England		(1936)*

Two physicians were licensed by endorsement after an oral examination on March 12 and April 2. The following schools were represented:

School	LICENSED BY ENDORSEMENT	Year Grad of	Endorsement
Rush Medical College		(1918) N. B. M. Ex.	
Harvard University Medical School		(1918) N. B. M. Ex.

Book Notices

The Physiological Basis of Medical Practice A University of Toronto Text in Applied Physiology By Charles Herbert Best M.A. M.D. D.Sc. Professor and Head of Department of Physiology University of Toronto and Norman Burke Taylor M.D. F.R.S. F.R.C.S. Professor of Physiology University of Toronto Cloth Price \$10 Pp 1 684 with 399 illustrations Baltimore William Wood & Company 1937

While this textbook will be of great value to the physician, it is doubtful that it will prove attractive to most medical students because of the unnecessarily voluminous text and the extraordinarily unoriginal and monotonous style. The authors proceed with no introduction into general physiology or exposition of biologic or physicochemical principles to discuss one of the most complex phases of physiology—the blood. Experience of most physiologists is that the more effective approach to physiology is through other less intricate phases of the subject. About a hundred pages of the text is occupied by bibliographic references. Out of more than 2,000 such individual references less than 100 are from literature in other than the English language. One wonders if this is a new expression of Anglophile nationalism or merely a concession to the average student's inability to read these languages. While the textual material is sound in content and for the most part well balanced as to proportionate amounts, there appears to be a somewhat inadequate discussion of sense organs. Possibly this is due in part to the fact that this material is intimately distributed through the section on neurophysiology, which is certainly an unusual method of presentation. Another weakness is the rather inadequate treatment of muscle physiology. The disparity between the sixteen pages devoted to this subject and the 178 devoted to blood and body fluids and the 100 odd pages allotted to the kidney is rather puzzling. The authors have introduced an innovation likely to be especially appreciated by the physician. After each section there is a discussion of the clinical applications of physiologic principles elaborated in the preceding pages. Illustrations are well selected and for the most part well reproduced. Many are obviously originally prepared for the text. Despite the defects mentioned, some of which are dependent on the fact that this is a first edition, the book will be a valuable reference work for any one.

Die Sternalpunktion als diagnostische Methode Von Professor Dr Hans Schulten Boards Price 18 marks Pp 82 with 18 illustrations Leipzig Georg Thieme 1937

There have been a number of short monographs on the subject of sternal puncture of recent publication in Europe. Few, however, have presented the subject as comprehensively in such a concise manner. The author discusses the advantages of sternal puncture as compared with trephine and section technic. The detailed technic is clearly stated and methods are described for the staining of the aspirated material. There is then a detailed discussion of the morphology and embryogenesis of cells of the sternal marrow. The author discusses the disagreement as to the nomenclature of the different young forms of red cells and adopts a classification based on cell size, reaction of the protoplasm to dyes, and the nuclear structure. He brings out the point that, while under normal conditions growth is regular and occurs through given stages, many irregular changes may take place in diseases that can be classified only with great difficulty. Controversial points are discussed in a broad manner and the various points of view are fairly treated. The author regards the Ferrata cell as an artefact but he feels that it has pathologic significance. Where the text permits crystallization in the form of diagrams and tables, this method of exposition is used. The origin of marrow cells is conveniently presented in diagrammatic form. The sternal marrow picture in the various diseases of the blood-forming organs is next considered. The detailed changes in treated and untreated cases of pernicious anemia are enumerated in detail. The author is of the opinion that sternal puncture by itself is of little value as a diagnostic procedure until pernicious anemia is well developed.

The primary and symptomatic anemias are then discussed with reference to sternal marrow changes. The author feels that polycythemia vera can be distinguished from the symp-

tomatic variety by the absence of characteristic appearances of the marrow in the latter condition. In infectious diseases, Schulten feels that the diagnostic and prognostic value of sternal puncture is not great. A short discussion is devoted to Pelger's familial nuclear anomaly. The condition is considered to be of little pathologic significance.

Eosinophilia is not taken up in great detail and the author tactfully advises that other sources of information be consulted to clarify the confusion that exists. The leukemias are considered in detail and this section is particularly well done. Schulten feels that sternal puncture is of definite value in establishing a more precise diagnosis and in differentiating different clinical and laboratory observations in which leukemia is simulated. There is an unsatisfactory knowledge of the sternal marrow changes in the group of lymphogranulomas so that little can be added at this time. Gaucher's disease is briefly but adequately discussed.

The author's contention that sternal puncture is of value in differentiating splenogenic medullary thrombopenias is open to question. It is not an unusual experience among those employing this procedure to find that megakaryocytes are frequently absent from smears of normal cases. In hemophilia the procedure is definitely contraindicated. The changes in metastatic carcinoma, lymphosarcoma and myeloma are next discussed. While there are a few controversial points in this monograph which the author treats dogmatically when he is without adequate proof, the reader will find the subject generally treated in as authoritative and lucid a manner as in any other text. It is well organized and edited and beautifully illustrated by diagrams and colored plates of cells that are encountered by sternal aspiration in health and disease. The illustrations alone are worth the price of the monograph. The work is highly recommended to the pathologist, hematologist and the clinician interested in diseases of the blood-forming organs.

Hay Fever with Special Reference to Treatment by Intranasal Ionization By Clive Shields B.M. B.Ch. Clinical Assistant Physiotherapy Dept St George's Hospital Cloth Price \$2 50 Pp 51 with 4 illustrations New York & London Oxford University Press 1937

The introductory sections on allergy and hay fever are very brief. So too is the section on the anatomy and physiology of the nose and sinuses. In his discussion on treatment the author advises against the use of local medication, such as ephedrine, since he states that the effects are only evanescent and the reaction usually makes the patient much more miserable than he has been before its use. He uses ephedrine plus a barbiturate internally. His method of nasal ionization is discussed in detail. Rather than giving one ionization for a long period, with a high current, he gives many ionizations for short periods with a low current. The contraindications to ionization which he observes are gross infection of paranasal sinuses unless proper drainage has been effected, gross nasal obstruction from markedly deflected septum, polypi, spurs and neoplasms, and dental sepsis or septic tonsils. Any of these conditions, if present, is treated first and, if necessary, ionization follows at a later date. The author uses a constant unidirectional current of from 15 to 20 volts and when the source is other than a battery he gives precautions and methods to prevent fluctuations in current. He includes a milliampere meter in the circuit and also a rheostat whereby the current can be raised gradually. The electrodes used are simple, made by bending zinc wire. The two sides of the nose are ionized at one time. This procedure is repeated at weekly intervals for four or five treatments the first year. If necessary, two or three treatments are given the second year and one or two the third year. Shields warns that adequate cocaine anesthesia is absolutely essential before proceeding with ionization, and he allows the cocaine to act at least fifteen minutes before he begins ionization. He carefully describes his method of packing the nose and states that when sloughs occur after ionization they are usually due to improper packing of the nose or to current alterations. In certain cases in which the proper packing of the nose is not possible, he uses the continuous irrigation technic. This consists of ionizing through a constantly flowing 2 per cent zinc sulfate solution. When this method is used the reactions from ionization are more severe. Shields is enthusiastic about zinc ionization and the results that he apparently obtains are unbelievably good. His claims

for the technic described are almost immoderate in their enthusiasm. He states that the complications of ionization that have been described by other authors, e. g., otitis media, anosmia and sloughing of the mucosa (considered a necessary result by American workers), are avoided with no decrease in beneficial effects by using his technic.

La perméabilité. En physiologie et en pathologie générale. Par Ernst Gellhorn professeur du physiologie au Collège du médecine de Chicago Université de Illinois (U. S. A.) et Jean Régner professeur agrégé à la Faculté du pharmacologie de Paris. Paper. Price 160 francs. Pp 928 with 42 illustrations. Paris: Masson & Cie 1936.

Permeability is of fundamental importance in biology and medicine. It has been and must continue to be the subject of research by those who would elaborate a physicochemical science of cell physiology. In the German edition (1929), Gellhorn studied about 1,400 references, in the French translation more than 100 more are added. The book is indeed more a collection and critical analysis of the literature than a contribution of original work, although it contains much that is original. In the translation, Régner gives original German in Roman letters, and his own comments, which are voluminous, in italics. The order of presentation is: Methods of study, direct and indirect. Permeability of membranes. Permeability of cells, vegetable and animal. Permeability of organs. Results and theories of permeability. Final considerations. Included under this outline is work in physiology, pathology, pharmacology and some envisagement of therapeutics. As an example of physiology, one may consider absorption, secretion and excretion, of pathology, edema and glaucoma, of pharmacology, anesthesia, of therapeutics, the permeability of immunizing agents.

In any subject the actual understanding of it is about in the inverse ratio of the square of the number of theories that would explain it. The authors emphasize only four: the lipid membrane theory, the colloid-chemical theory, the theory of adsorption and the theory of ultrafiltration. They conclude that no one theory will explain all the facts. An explanation may be given by a fusion of several theories, the fusion, however, may have to differ for different cells. A great drawback to the book is the lack of an index. It is divided into forty-one chapters. Neither the content of these nor the general subject matter is indexed. Without the index, however, this monograph is a valuable contribution. It is a great aid to research workers. Any one interested in the important subject of permeability will find the literature and an analysis of it presented in a manner as acceptable and complete as the present knowledge of the subject permits.

Internal Diseases of the Eye and Atlas of Ophthalmoscopy. By Manuel Uribe Troncoso M.D. Instructor in Ophthalmology College of Physicians and Surgeons Columbia University, New York. Cloth. Price \$15. Pp 530 with 239 illustrations. Philadelphia: F. A. Davis Company, 1937.

The newer textbooks in medicine have made a definite attempt to correlate pathology with clinical symptoms. In the preface to this volume the author states that "success in teaching is due chiefly to the method of presenting the subject. The more scientific approach is first to emphasize the pathologic changes and physiopathology of the disease, and then endeavor to deduce the symptoms from the lesions." The ophthalmologist has the advantage of being able to study structural changes in the course of their development and to observe the different stages and final results objectively from the exudate to atrophy, from vascular changes to hemorrhage and connective tissue development, while in other parts of the body the pathologic changes have to be reconstructed from specimens of dead tissues. It is important, therefore, that the student should be taught how to correlate the ophthalmoscopic symptoms with the pathologic lesions, trying to visualize the changes going on in the structures and thus to forecast their final results. Such a commendable task is difficult of accomplishment with mere word descriptions, which must of necessity be short, together with illustrations in black and white and others colored on the flat pages of a book. The new terms retinosis and choroidosis are of a certainty better than retinitis and choroiditis, in which no inflammation is evident, but the question as to whether these terms are better than retinopathy and the like must remain for choice and usage to decide. The technic of ophthalmoscopy and the structural features of the internal eye are adequately discussed. The basic factors in the understanding of visual field

determinations is thoroughly set down. The main features of developmental anomalies and vascular physiology and pathology of the eye are well emphasized. Disease and its consequences affecting the optic nerve, the retina and the choroid have by description and illustration aided in the comprehension of the changes by vividly portraying objective evidence to the student. Short chapters on vitreous changes and those due to injury of the various tissues of the internal eye complete the volume. The illustrations in black and white are excellent, while the colored pictures have a decided tendency to exaggerate the condition depicted. While there is frequent mention of the name of authorities, there is a definite loss in the omission of a bibliography. Many of the newer contributions, which one might expect to find in a work so recently from the press, are found wanting. Certainly it may be said that the author has contributed a useful and pertinent work which brings together much to the physician interested in diseases of the internal eye and the effect of general disease on these structures.

Vitamins Minerals and Hormones. By Albert P. Mathews. Andrew Carnegie Professor of Biochemistry University of Cincinnati Cincinnati, Ohio. Reprinted from Principles of Biochemistry by the same author. Cloth. Price \$1.50. Pp 97. Baltimore: William Wood & Company, 1937.

Three chapters from the author's larger Principles of Biochemistry are here reprinted in the form of a convenient volume. It is unfortunate that some information is presented without bibliographic references. There are also occasional statements of dubious importance, for example, it is said (page 19) that "corn silk extract has long enjoyed a reputation of value in treating obstinate cases of cystitis. Whether its use for this purpose depends upon its vitamin B₁ content is, however, undetermined." The chapter on mineral metabolism is inadequate, even for an elementary presentation. The chapter on hormones is brief and might be useful as an introduction to the chemistry and physiology of the subject.

Alkoholfachweis bei Verkehrsunfällen. Von Dr. Kurt Hoffmann. Oberfeldarzt der Polizei beim Sanitätsamt des Chefs der Ordnungspolizei im Reich und Preussischen Ministerium des Innern. Mit einem Vorwort von Generalarzt der Polizei Dr. Kloster. Erweiterter Sonderdruck aus Neue Deutsche Klinik. Handwörterbuch der praktischen Medizin. Band XIV. Herausgegeben von Prof. Dr. R. Cobet und Prof. Dr. K. Gutzeit. Paper. Price 2.50 marks. Pp 56 with 3 illustrations. Berlin & Vienna: Urban & Schwarzenberg, 1937.

The value of the determination of alcohol in the blood in persons involved in automobile accidents is presented here in the light of the experience of the Prussian police department in about 3,600 instances analyzed with the micromethod of Widmark. The author gives a brief discussion of the general problem of traffic accidents, classifying the half million accidents reported according to the vehicle involved, the age and sex of persons killed and injured, and the apparent cause of the accident. The increasing fatality rate from traffic accidents is pointed out, and the importance of alcohol in contributing to this figure is emphasized, 8,679 drivers having been found to be under the influence of alcohol.

The clinical effects of alcohol on the central nervous system, the psyche, the reaction time, motor and sensory activity, pulse rate, pupillary reactions, ataxia, appearance, conduct, orientation and ease of performance and the difficulties in clinical diagnosis, the effects of diseases, habituation, or injuries, and the significance of the odor of alcohol in the breath and in the urine are briefly presented. The quantitative methods for the determination of alcohol in other materials are lightly dismissed and the Widmark method for the determination of the alcohol content of a drop of blood collected in a capillary tube is described in detail. The special capillary tubes for this purpose with their rubber stoppers were distributed widely in Prussia and the specimens taken in increasing numbers.

Analysis of the results shows that a clinical diagnosis of "under the influence of alcohol" was obtained in less than 10 per cent of the instances with a concentration of alcohol in the blood of less than 0.04 per cent but in increasing frequency above this figure, reaching over 90 per cent in those with 0.18 per cent and 100 per cent of those over 0.3 per cent. The inaccuracy of the clinical diagnoses rendered by 574 different physicians is stressed and the conclusion drawn that the chemical data are in good agreement with the clinical observations. The distribution of cases by day of the week, time of day, age and

occupation show interesting differences. Sources of error in the determinations, such as the differences between venous and capillary blood, the danger of using tincture of iodine or some other alcoholic solution in disinfecting the skin before drawing the blood, titration and other technical errors, and the possibilities of interference by the 0.003 per cent alcohol found in normal blood or by acetone or other volatile organic materials in the blood, as well as the role of carbon monoxide in the blood of motorists are critically considered. The effect of insulin on the alcoholic concentration in the blood, described by Bickel and his co-workers, is held to be still without clinical verification in man, but the danger of insulin poisoning in the causation of traffic accidents and its differentiation from alcoholic intoxication are emphasized.

Social and medicolegal aspects of the use of alcohol, and the determination of alcohol in the blood of all involved in automobile accidents, as described in Prussia, differ markedly from those which would be encountered in this country, but the rich clinical and laboratory experience described in this work should go far toward establishing the validity of the chemical determinations in the diagnosis of acute alcoholic intoxication.

Cosmetic Dermatology With Dictionary of Ingredients. Discussion of Anatomic, Physiologic and Pharmacologic Bases of Cosmetic Application. 'Shelf Tested' Formulary and Appendices on Odor and Color in Cosmetics. By Herman Goodman, B.S., M.D. Cloth. Price \$6.50. Pp. 591. New York & London: McGraw-Hill Book Company, Inc. 1936.

It takes a stretch of the imagination to call this book a dermatology. The volume is divided into two parts, the first containing a list of substances used in dermatology, and the second a set of recipes for what might be called beautifying cosmetics on the one hand and preparations definitely medicinal in nature on the other. At times there are limited and elementary discussions on lesions and treatment. There are no illustrations and no references to the literature. In appendix A is found a list of cosmetic colors. The volume will be found of value to certain dermatologists and to cosmetic manufacturers. It covers about the same ground as the *Lexicon der kosmetischen Praxis* by Volk and Winter but is not as complete.

Physical Diagnosis By Ralph H. Major, M.D., Professor of Medicine in the University of Kansas. Cloth. Price \$5. Pp. 457 with 127 illustrations. Philadelphia & London: W. B. Saunders Company. 1937.

This book is well written, well constructed and exceedingly well illustrated. It is interesting reading because, as the author states, he "has made free use of quotations, partly because of an interest in classic description and partly because of the excellence of these early accounts." The subjects of temperature and fever are usually omitted in textbooks of physical diagnosis and their inclusion is commendable. Another welcome addition is a short explanation of the physics of sound. The author's failure to discuss incipient tuberculosis in the chapter on diseases of the lung is subject to criticism. His failure to devote as much space to a discussion of roentgen rays in the diagnosis of diseases of the lung as to the roentgen rays in the diagnosis of diseases of the heart and abdomen may give a wrong impression to the student as to the relative importance of the roentgen rays in the diagnosis of diseases of the lung. The chapter on history taking and recording is the last one and in general the discussion and outline follow the conventional rules. Since social, domestic and economic factors are now well recognized as having an important bearing on the entire clinical history, a statement of their importance should have been included and the student's attention directed to them. Despite these few faults, Dr. Major has succeeded in presenting an unusually vivid textbook of physical diagnosis which should hold the interest of the medical student.

Complement or Alexin By T. W. B. Osborn, University of the Witwatersrand, Johannesburg. Cloth. Price \$3. Pp. 116. New York & London: Oxford University Press. 1937.

This monograph reviews the writings about complement, the thermolabile element in the blood which in combination with specific immune bodies causes the destruction of bacteria and foreign red cells. After the introductory consideration come chapters on the constitution of complement, the scope of its activity, factors influencing its action *in vitro*, the nature of its action and possibly related phenomena, its presence in the blood stream, its origin in the body and its variations *in vivo*.

In discussing the constitution of complement the author calls the midpiece and the endpiece "midstuk" and "endstuk," but there seems to be no need for any such words in English. Throughout the book Friedberger is misspelled Friedberger. The book will be helpful to students of complement. It records the slow advance in our understanding of that principle by exhaustive research, although it is forced to catalogue many discordant results. One may well agree with the author when he states that the impression is left "that too many contributors have been eager for quick practical results, too many have tried to short-cut the more academic fundamental problem, and too many have used inaccurate methods of estimation and inefficient controls. There is a feeling abroad that the obscurities will remain until the biochemist and the biophysicist are enticed and encouraged to join in the work."

An Introduction to General Practice By E. Kaye Le Fleming, M.A., M.D., Chairman of Council, British Medical Association. Cloth. Price \$2. Pp. 150. Baltimore: William Wood & Company. 1936.

This book has little interest for the older practitioner but has a certain value for the person who is just about to enter the general practice of medicine, for whom it is intended. It contains advice relative to his conduct toward other physicians, patients, hospitals and druggists, and discussion of certain legal problems. There is a rather sketchy chapter concerning the doctor and finance. The value of the book in this country is somewhat impaired by its purely British background, but it will furnish something of value to the senior student and the intern.

Source Book of Orthopaedics By Edgar M. Bick, M.A., M.D., Adjunct Orthopaedic Surgeon, Hospital for Joint Diseases and Mt. Sinai Hospital, New York. Cloth. Price \$4. Pp. 376. Baltimore: Williams & Wilkins Company. 1937.

The author has written a comprehensive history of orthopedic surgery. The book is a real contribution to the medical literature of the world and will act as a stepping stone for the future history of orthopedics. Starting with primitive man and ancient practice, it covers the renaissance, the seventeenth and eighteenth centuries and the modern period. The author is a medical historian and has evolved a one volume book which reveals extensive research and infinite patience. Orthopedic conditions and therapy are traced from primitive times to the present day. The fluctuation of knowledge and factors that resulted in progress or the reverse are elucidated. Descriptions of orthopedic conditions are woven into the history in a chronological manner, and the modification of theory and practice through the centuries is discussed. The bibliography of orthopedic literature is exceedingly complete. One can at a glance determine the historical background of most orthopedic conditions. The book is valuable because it is a history of orthopedic surgery, a reference library of orthopedic literature and a bird's eye view of the specialty. It simplifies the task of preparing a paper on an orthopedic condition.

Traité de chirurgie orthopédique Publié sous la direction de L. Ombredanne et P. Mathieu. Secrétaires de la rédaction: M. Lacroix, G. Huc et P. Padovani. Tome 1. Cloth. Price 300 francs. Pp. 504 with 433 illustrations. Paris: Masson & Cie. 1937.

This is the first of a five volume set on orthopedic surgery edited by two of the leading orthopedic surgeons of France and written by sixty-four well known collaborators. The first volume contains a discussion on physiology, pathology and therapeutics in general. Orthopedic surgical treatment and its evolution are described. Congenital malformations of the extremities, including their development, congenital hypertrophy defects and deformities due to amniotic disturbances and aplasia are discussed. The normal and pathologic histology of bone substances and bone structure, reparative ossification and heterotopic ossification closed and open fractures, fractures with malunion, compound fractures, fractures with vicious consolidation and pseudarthrosis, traumatic separation of the epiphyses, osteomyelitis in adolescents and osteomyelitis in infants are considered. The second part contains a discussion on the spine and the lower extremities. There is a section on amputations and procedures to equalize the length of the legs and a small section on shoes and the disabilities following injury. The section called amniotic lesions is well handled. There is a creditable section on chronic osteomyelitis. The illustrations are appropriate and beautifully reproduced.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Medical Practice Acts Assisting Unlicensed Person to Practice Medicine—The medical practice act of New Jersey prohibits the giving of aid or assistance to "any person not regularly licensed to practice medicine or surgery in this state." The state board of medical examiners instituted proceedings against the defendant, a physician, charging that he had violated the foregoing prohibition. In the trial court the defendant moved to dismiss the complaint on the ground that the prohibition against aiding unlicensed persons to practice medicine did not apply to a licensed physician. With this contention the trial court agreed, dismissed the complaint, and entered final judgment for the defendant. The board thereupon sought a review of the ruling in the supreme court of New Jersey.

The defendant's contention, said the court, was that the prohibition merely indicated a legislative intent to protect the public at large from being treated by an unlicensed person and that if the legislature had intended to punish a licensed physician for giving aid or assistance to an unlicensed person it would have provided for the revocation of such a physician's license. A physician, it was further argued, cannot aid or assist any one unlawfully to practice medicine, because in responding to a call made on him professionally he is actually engaged in the practice of medicine and is necessarily doing that which he has a perfect right to do. But, said the supreme court, the prohibition applies to "any person," and a licensed physician certainly comes within the phraseology used. The fact that the legislature did not designate the giving of such aid or assistance as a cause for revoking a physician's license did not, the court thought, foreclose the application of the prohibition to a licensed physician, the legislature may have concluded that the act of giving such aid was not sufficient cause for the revocation of a physician's license yet should not go entirely unpunished.

There are many cases in other jurisdictions, the court pointed out, in which the revocation of a physician's license for aiding an unlicensed person has been sustained. True, the issue at bar does not relate to the revocation of a physician's license, it relates to the imposition of a penalty on a licensed physician. The basic question, however, that is, whether a licensed physician can be guilty of aiding or assisting an unlicensed person to practice medicine or surgery, is present in each instance. The resultant statutory penalties only are different. The question to be decided in each case is: Did the licensed physician, as such, treat the patient, or did he merely give aid or assistance to an unlicensed person to practice medicine or surgery? In the former circumstance, the prohibition in the medical practice act would not apply, in the latter, it would apply. The facts of each case must necessarily control the answer. The trial court refused to permit the prosecution to present the facts and in doing so committed a reversible error. The judgment of the trial court was therefore reversed and the case remitted for further consideration.—*State Board of Medical Examiners of New Jersey v. Wallen* (N. J.) 188 A 449.

Medical Practice Acts Naturopathic Applicant Not Qualified for License—The appellant, Harold A. Davis, applied to the state board of medical registration and examination of Indiana for a certificate authorizing the clerk of the Marion circuit court to issue him a license to practice naturopathy. With this application, Davis submitted a diploma issued to him by the College of Drugless Physicians, purporting to confer on him the degree of Doctor of Naturopathy. The board refused to issue the certificate and after the superior court upheld the action of the board Davis appealed to the appellate court of Indiana, in banc.

According to the evidence, Davis was born Nov. 16, 1911, and attended public school to and including the third grade and parochial school after that until he had completed the eighth grade. He thereafter spent one term in a parochial high school. On Sept. 9, 1925, when he was 13 years and 9 months old,

Davis entered the College of Drugless Physicians, also referred to in the record as 'Briggs School,' at which time he was still a student in the grade schools during the day. On Nov. 16, 1926, on the day he was 15 years of age he received the degree of Doctor of Naturopathy from the college, after having attended it only one year, two months and seven days. The evidence further disclosed that the school had been closed by the courts and that Briggs was convicted of operating a diploma mill. The board refused to issue the certificate because of Davis's immature age at the time he attended the college and because the school of graduation did not comply with the standards established by the board.

The medical practice act of Indiana authorizes the board of medical registration and examination to establish a schedule of minimum requirements and rules for the recognition of medical colleges. An amendment to the medical practice act was enacted in 1927, providing in part as follows:

Provided That any chiropractor or practitioner of any other system or method of healing who is a graduate of a school or college teaching the system or method of healing which he practices and who was on January 1, 1927, residing in the state of Indiana and practicing chiropractic or any other system or method of healing taught by the school or college of which he is a graduate shall be given without examination a certificate for a license to practice the system or method of healing in which he has been so engaged.

Davis contended that under this amendment he was entitled to a certificate because he was on Jan. 1, 1927, a graduate of a school or college teaching a system or method of healing, at which time he was residing in Indiana and practicing the system or method in which he had been taught by the school or college. The medical practice act, said the court, must be construed as a whole to determine the intent of the legislature and the meaning of the language used in the various amendments that have been enacted. At the outset, in 1897, the legislature enacted legislation to regulate the practice of medicine, surgery and obstetrics. Subsequent to that time there were those who sought to evade the requirements of the act and as a result many new cults grew up. To meet this situation, various amendments were enacted in an effort to make the act broad enough to cover every method of practice. The legislature gave to the board the specific right to prescribe rules and regulations for schools which asked recognition from the board and it necessarily follows that a school which does not meet the requirements of the board is not a school within the meaning of the act. Since Davis did not present to the board satisfactory evidence that he was a graduate of such a school, he was not entitled to a certificate. The judgment of the superior court for the board was therefore affirmed.—*Davis v. State Board of Medical Registration and Examination* (Ind.), 5 N. E. (2d) 125.

Malpractice Death Resulting from Chiropractic Treatment for Headache—This is the fourth opinion rendered by the Supreme Court of Florida in this case.¹ Briefly, Foster, a chiropractor, undertook to treat Mrs. Thornton for a chronic headache by daily chiropractic "adjustments." During the last "adjustment" he sharply twisted her neck and she immediately felt an excruciating pain in the back of her head and neck. She became nauseated, vomited and fainted. A nonsectarian physician was summoned and administered a hypodermic of morphine. About an hour later another nonsectarian physician found her in a comatose condition. Her pulse was weak, she was cold and clammy, the pupil of her left eye was dilated, that of her right eye was contracted. Two weeks later she died. An autopsy indicated that death was caused by a hemorrhage resulting from a ragged tear about three-fourths of an inch long in the left lateral sinus. The patient's husband then sued the chiropractor. In this trial of the case the jury returned a verdict for the husband for \$20,670, which was reduced by remittitur to \$10,670, and the chiropractor appealed to the Supreme Court of Florida.

The principal question involved was whether or not the jury was warranted in assuming from the evidence that the chiropractor applied undue force and failed to exercise the degree of care required by chiropractic standards in treating the deceased. For the plaintiff, a nonsectarian physician testified

¹ Malpractice Death Resulting from Chiropractic Treatment for Headache. J. A. M. A. 103:1260 (Oct. 20) 1934. Malpractice Cerebral Hemorrhage Attributed to Chiropractic Adjustment. *ibid.* 103:1714 (Nov. 23) 1935.

that he had some degree of learning in the "chiropractic art," had made adjustments in conformity with chiropractic methods and was familiar with the degree of care required of chiropractors in making adjustments like the one in question. In his judgment, the injury to Mrs. Thornton was caused by a negligent application of undue force by the chiropractor. Another nonsectarian physician, a neurologist, testified that there was no possible explanation for the injury to Mrs. Thornton except the negligent adjustment given by the chiropractor. Several other nonsectarian physicians testified that a lesion in the brain would often cause symptoms such as those exhibited by Mrs. Thornton immediately after her injury. In their judgment the lesion in this case could not have been caused by a disease condition of the brain or in removing the brain in the course of the autopsy. The chiropractor contended that before his negligence could be established evidence must be adduced through the testimony of chiropractors concerning the standard of care required in making an adjustment like the one complained of and to prove that in treating Mrs. Thornton he negligently departed from that standard of care. But, said the Supreme Court, the rule contended for by the chiropractor does not exclude the testimony of physicians of other schools when that testimony bears on a point on which the principles of the schools of healing do or should concur. There was no question that the treatment given Mrs. Thornton was approved by chiropractic theory. The only question to determine was whether a recognized treatment was negligently administered. The determination of the trial court that the witnesses were qualified cannot be disturbed unless the determination was clearly erroneous.

The chiropractor contended further that the trial court erred in admitting certain statements in evidence alleged to have been made by Mrs. Thornton to her husband and to a nonsectarian physician immediately on regaining consciousness after the last adjustment. Declarations, said the court, that are natural emanations or outgrowths of the act in litigation, although not precisely concurrent in point of time, are admissible as part of the act or transaction if they are voluntarily and spontaneously made so nearly contemporaneous as to be in the presence of the transaction which they illustrate and explain, and if they are made under such circumstances as necessarily exclude the idea of design or deliberation. The statements complained of were made immediately after the patient regained consciousness, were the outgrowth of the transaction and were explanatory of it, they excluded any idea of design or deliberation, and they were corroborated by the evidence of several other witnesses. They were therefore admissible.

The judgment against the chiropractor was affirmed.—*Foster v. Thornton (Fla.) 170 So 459*

Malpractice Amputation Following Fracture Attributed to Physician's Negligence—The plaintiff, aged 13 years, sustained a compound fracture of his left arm, June 22, 1933. The defendant, a physician, was called to attend him and treated him at home until June 29, when he was removed to a hospital. In the meanwhile, gas gangrene infection had developed and amputation of the arm was necessary. The plaintiff thereupon sued the defendant and, from a verdict of the jury in favor of the defendant, the plaintiff appealed to the Supreme Court of Errors of Connecticut.

The plaintiff contended that the trial court erred in charging the jury as follows:

In order to recover the plaintiff must show not only that the physician or surgeon was negligent or unskillful but also that the injury resulted directly from such negligence or unskillfulness. No recovery can be had if there was any intervening cause in the absence of which it is reasonably probable that the plaintiff would not have suffered injury from the wrongful act or negligence. must have been a substantial contributing factor in producing the injuries complained of. Even if [the defendant] was negligent in some respect but that negligence didn't result in these injuries your verdict must be for the defendant.

The plaintiff's main contention was that the nature of the proof of causation in malpractice suits is peculiar and exceptional, and that recovery should be allowed if the negligence or unskillfulness of the defendant "deprived the plaintiff of the chances of a better recovery presumed to flow from proper treatment." Except as to speculative considerations involving mere possibilities in the course of the train of circumstances leading up to the final result, said the Supreme Court of Errors, the effect

of negligent treatment by a physician on the chance of the patient for a better recovery is necessarily included in the inquiry which was directed by the charge given by the trial court. Necessarily, if the jury found that the result was not as favorable as it would have been but for unskillful or negligent treatment by the defendant, they would have to find, under that instruction, that it was a "substantial contributing factor in producing that result." The injuries alleged by the plaintiff in the complaint included the development and progress of infection as well as the amputation of the arm, all of which are alleged to have resulted from negligent treatment by the defendant. Under the charge as given, the jury were in effect instructed that if they found the negligence of the defendant was a substantial factor in producing any of these injuries the plaintiff was entitled to recover therefor, otherwise not.

The trial court, continued the Supreme Court of Errors by using the word "contributing," sufficiently signified and emphasized that negligence, to impose liability for the consequences complained of, need only to have constituted a cause which contributed thereto substantially. As applied to the alleged negligence of a defendant, "contribute" or "contributing" signifies a causal connection between injuries and negligence which transcends and is distinguished from "those negligent acts or omissions which play so minor [a] part in producing the injuries that the law does not recognize them as legal causes." If the chain of causation of the damage, when traced from the beginning to the end, includes an act or omission which, even if wrongful or negligent, is or becomes of no consequence in the results or so trivial as to be a mere incident of the operating cause, it is not such a factor as will impose liability for those results.

The court could find no error in the record.—*Connellan v. Coffey (Conn.), 187 A 901*

Workmen's Compensation Acts Heat Stroke from Exposure to Temperature of 68 Degrees Fahrenheit—The claimant, an employee of the Southern Ice & Utilities Company, was ordinarily employed in an ice house where the temperature was approximately 28 degrees Fahrenheit. He contended that he suffered an accidental injury in the nature of heat exhaustion when he went from the ice house out into the open, where the temperature was approximately 68 degrees Fahrenheit. The state industrial commission allowed compensation and the company appealed to the Supreme Court of Oklahoma.

The company contended that it was utterly impossible for the claimant to have sustained a heat stroke under such circumstances. It presented what the court referred to as a very logical survey of authorities and argued that the court should take judicial notice of the fact that when the employee walked from a room averaging 28 degrees into the outside to work on pipes in a temperature not more than 70 degrees there could not possibly be a sunstroke. But, the court said, the physician testifying for the claimant stated that the injury was occasioned by change in temperature which resulted in heat exhaustion similar to sunstroke. In the opinion of the Supreme Court, therefore, the industrial commission had competent medical testimony on which to base its finding.—*Southern Ice & Utilities Co. v. Barra (Okla.), 62 P (2d) 988*

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers in continental United States and Canada for a period of three days. Periodicals are available from 1926 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Occurrence and Pathogenesis of Cardiac Hypertrophy in Graves Disease. C. K. Friedberg and A. R. Solval. New York—p. 599

Thrombo-Anguitis Obliterans in Negroes—Yater declares that the clinical correlation of his five cases in Negroes with cases of thrombo-anguitis obliterans occurring in Caucasians is not so great as are the pathologic similarities. Nevertheless, the clinical histories are not incompatible with the diagnosis of that disease. All five patients were smokers, two of them more than moderate addicts of this habit. All were relatively young men. The history was one of chronic peripheral vascular disease in three cases, and typical intermittent claudication occurred in two. Buerger, and Brown, Allen and Mahorner have described cases of thrombo-anguitis obliterans in Caucasians presenting histories quite similar to those of these five cases. Physical examination gave incontrovertible evidence of bilateral and extensive occlusive vascular disease in the lower extremities in all five cases. Arteriograms were typical of thrombo anguitis obliterans as seen in the white race, and the oscillometric studies in two cases confirmed the closure of all large arteries bilaterally. The nature of the gangrene in all cases was similar to that seen in thrombo-anguitis obliterans. Pathologically, all five cases were typical examples of the advanced stage of the disease. In three cases the veins were affected as well as the arteries. In the other cases only the dorsalis pedis artery was studied by means of biopsy of this vessel. None of the lesions were in the active stage of the disease. The lesions in the arteries were more suggestive of panarteritis than simple inflammation of the intima. Syphilis has been excluded as a prominent or specific cause of Buerger's disease. All five patients undoubtedly had, or had had, syphilis. Although special studies did not reveal the spirochete, its absence is not sufficient to eliminate it as the pathogenic organism in the healed stage of vascular disease represented. The lesions are not suggestive of syphilis. It is conceivable that in susceptible individuals the toxins of the spirochete might produce such vascular lesions or even that the end stage of actual spirochetal invasion might present such a pathologic picture.

The Heart After Severe Diphtheria—Thompson and his co-workers reexamined ninety-one of 100 persons who had severe diphtheria from fifteen to twenty years ago. No clear instance of auriculoventricular or intraventricular block was found. There were three cases with auriculoventricular conduction at the upper limit of normal (PR interval, 0.2 second) and four cases in which there is a possibility that there may have resulted a slight interference with intraventricular conduction. In two of the three former cases the PR interval is greater than it was at the time of a previous follow-up examination ten years before, and in the four latter cases the width of the QRS complexes is slightly greater in two cases than it was ten years before, but in no case is true abnormality a cer-

tainty. In two of the three cases with PR intervals of 0.2 second there was strong suspicion that there had been an intercurrent rheumatic infection. While there are acceptable cases of the development of disturbed conduction during the course of diphtheria and in very rare cases the disturbance persists permanently, there is as yet no proof that it may develop some years after the illness.

*Flocculation Method for Diagnosis of Active Tuberculosis. F. Rytz and G. K. Higgins. Minneapolis—p. 264

Flocculation Method for Diagnosis of Tuberculosis—Rytz and Higgins outline a simple serologic reaction that differentiates with reasonable accuracy and aids in the detection of early active tuberculosis. The test is of a nonspecific nature, as a simple alcohol-saline mixture serves as antigen. However, Lehmann-Facius and Steinert have shown that in tuberculous infections the euglobulin may acquire antigenic properties and combine in vitro with the antibody. On that basis it would be explainable why the present reaction and other tests may become negative in severe cases of active tuberculosis when great numbers of disintegrated tubercle bacilli and other cell substances possibly enter the circulation to combine with the antibody of the blood stream. The free antibody of the circulation, ordinarily causing a reaction, may thus be combined and unable to unite in vitro with antigenic protein, or other antigenic substances, possibly activated by alcohol-saline solution. The antigen is prepared from ground tubercle bacilli (H37) that had been grown on glycerol-agar. The serum must be free from hemolysis and blood cells, and the sample should not be more than two days old. Of the 860 serums tested, 175 were from patients in tuberculosis sanatoriums. By clinical classification 121 were from patients with active tuberculosis and thirty-nine of the group were clinically defined as borderline cases. Blood samples were also taken from fifty-four tuberculous patients, clinically classified as arrested, forty-nine of whom gave negative reactions. In a comparatively small number of severe and hopeless cases of active tuberculosis, the test had become negative in about 50 per cent. In 80 per cent of the total number within the group of tuberculous patients the serologic observations agreed with the clinical classification.

Circumscribed Osteoporosis of Skull and Paget's Disease—Kasabach and Gutman present fifteen cases of circumscribed osteoporosis of the skull together with follow-up studies on seven cases reported previously by Kasabach, Dyke and Schuller. The roentgenologic, clinical, pathologic and biochemical characteristics of the disease are summarized, so far as the data in the literature and their own material permit. The progress of the disease has been studied for periods of

from three to thirteen years. In reconstructing the development of the bizarre patterns seen in advanced stages, it would appear that the disease begins as small, rounded, circumscribed areas of osteoporosis, often in the frontal region near the base, sometimes in the occipital region, occasionally elsewhere. These areas expand over a period of years until the major portion of the calvarium or the entire calvarium is involved. Since the initial foci originate near the base, the last remnant of normal bone is likely to be in the parietal region posterior to the vertex, producing a characteristic design in the lateral roentgenogram of the skull. In thirty-two of the forty-seven cases (including eleven of the present cases) circumscribed osteoporosis of the skull was associated with typical Paget's disease somewhere in the skeleton. In eighteen cases the skull was the site of both circumscribed osteoporosis and the "cotton wool" shadows characteristic of Paget's disease. In five cases presenting only osteoporosis of the skull follow-up studies revealed the development of Paget's disease in or about the osteoporotic areas within two to eight years. Thus appears to be a regular sequence, though the areas of circumscribed osteoporosis may remain essentially unchanged for a number of years. Most cases are asymptomatic. In some, headache, vertigo, migraine and epileptiform attacks may have been related to the osteoporosis. The peak age incidence of circumscribed osteoporosis occurs two decades earlier than in Paget's disease. In the chemical analyses of the blood, with one exception, the serum calcium and inorganic phosphorus were within normal limits. Serum phosphatase activity was essentially normal in osteoporosis but was characteristically elevated when typical Paget's disease was also present. The results of pathologic changes of bone from osteoporotic areas are similar to and probably identical with those described in what Schmorl called "hemorrhagic infarction of the calvarium." There is no definite evidence now available to indicate whether vascular or the bony changes are primary. It is believed that circumscribed osteoporosis is not an obligatory, early phase of Paget's disease but a precursor of Paget's disease or, in a broad sense, an atypical form of Paget's disease as suggested by Sosman. Its occurrence solely in the skull is thought to be related chiefly to the peculiarities characterizing the diploic circulation and the cranial architecture.

Serum Disease of Nervous System—Kraus and Chaney confine their discussion to serum disease of the nervous system. The cause of the disorder in question is an allergic or anaphylactic reaction in the body due to a foreign serum. The specific antitoxins in the serum play no part. The neuropathologic changes associated with serum sickness are the same as those which appear elsewhere in the body and consist of a primary disorder of the blood vessels, causing nutritive impairment of the tissues of the nervous system and interfering temporarily as a rule with the activity of the nerve fibers and cells but occasionally causing cell death and parenchymal necrosis. Serum sickness involving the nervous system produces a group of syndromes almost as varied and numerous as syphilis or lethargic encephalitis. Though the pathologic process is reasonably well defined, there is still no adequate explanation of the widely different sites of involvement in the various cases reported. There may be moderate or high fever, urticaria either generalized or limited to the region of the injection or to other

regions, pain, swelling and increase in temperature of one or many joints, enlargement and painfulness of the lymph nodes, severe neuralgia in one or several extremities, headache, nausea and vomiting. After the initial onset the picture varies according to the syndrome that appears. There is no relation between the site of injection and the site of the disease of the nervous system. The syndromes may be divided into cerebral, spinal, radicular and neural. As a rule recovery occurs, though months may be needed for complete cure. Occasionally paralysis and weakness, complete or partial, of one or several muscles may remain. The pain that is present at the onset usually disappears within a week. Such drugs as atropine and epinephrine are indicated both for the serum sickness and for the resulting paralysis. Massage and electrical therapy are indicated in the presence of muscular paralysis and wasting. Three new cases are reported. In spite of the complications of therapeutic serums, use should be made of them when they are indicated for the prevention or cure of the specific disease.

Histologic Study of Ameloblastoma—Robinson states that cystic, cystic and solid, and solid forms of ameloblastoma are encountered. Cornification, hornification or epithelial pearl formation may be found occasionally in the ameloblastoma, as in one of the cases that he cites and in fifteen instances collected from the literature. While no single ameloblastoma has yet been traced from the solid to the cystic form through histologic studies, it seems highly possible that such a transition takes place. The solid ameloblastoma closely resembles the developing tooth up to the point at which generative processes should begin. From this point on, a graded series of degenerative changes with cyst formation in the stellate reticulum can be noted in the neoplasm. This degeneration from solid to cystic was noted by Kronfeld (1930) in a series of ameloblastomas, and his observation is confirmed by the author's study. While this evidence is highly suggestive, it cannot be asserted that such a process is known to take place.

Isolation of Probable Pathogenic Staphylococci—Chapman and his colleagues describe a medium that was developed to simplify the search for pathogenic types of staphylococci On this medium about 98.5 per cent of strains of the pathogenic type of staphylococcus grew luxuriantly while about 94 per cent of the nonpathogenic type were inhibited This medium should be useful for isolation purposes, particularly when a large series of cultures is to be tested The positive in vitro reactions of strains isolated from pus obtained from sinuses, osteomyelitic lesions, boils, carbuncles and the like, and the correlation of the three in vitro properties in a large series of strains indicated that hemolysis, coagulase and crystal-violet agar tests could be applied as in vitro indicators of probable pathogenicity The simultaneous use of several in vitro tests, each of which correlated with rabbit inoculation tests, increased the accuracy of interpretation of the results Search for a medium containing a dye that would differentiate pathogenic from nonpathogenic strains, and yet not inhibit pathogenic strains, led to bromthymol blue agar Best results are obtained when the concentration of the dye is increased to 0.17 Gm per liter To determine whether this concentration of brom-

thymol blue had an inhibitive effect on pathogenic types of staphylococci, swabs from the nose, throat and gum margins of patients suspected of having chronic diseases were plated on proteose lactose agar containing 0.017 per cent bromthymol blue Duplicate swabs were plated on rabbit blood agar Parallel results were obtained in sixty-nine of ninety-six pairs of swabs and widely different results were obtained in only three pairs Except for a few intermediate size colonies of in vitro negative strains, those strains which grew produced colonies as large as those on ordinary mediums

Immunization Against Poliomyelitis with Ricinoleated Vaccine—During the last year Kolmer and Rule have immunized 130 additional rhesus monkeys with ricinoleated vaccine for the purpose of further determining its effectiveness in protecting these animals against intracerebral and intranasal inoculation with multiple infective doses of poliomyelitis virus, to compare the effectiveness of subcutaneous and intracutaneous routes of administration and to secure more information on the safety of the vaccine by determining the number or percentage of animals developing paralysis from subcutaneous and intracutaneous injections during the period of immunization Of eighty monkeys receiving from five to ten subcutaneous injections of vaccine in doses ranging from 0.05 to 1 cc per kilogram every five days, sixty-one, or 76.5 per cent, were found to have acquired effective resistance to intracerebral inoculations of virus The occurrence of acquired resistance induced by from five to ten doses of from 0.05 to 0.4 cc per kilogram varied from 64 to 75 per cent, while doses of 0.5 and 1 cc per kilogram completely protected from 93 to 100 per cent of a group of twenty one animals Of seven additional monkeys given five subcutaneous injections of the vaccine in doses varying from 0.1 to 1 cc per kilogram, five were found protected when inoculated intranasally two weeks after the last dose with 0.5 of 10 per cent virus (two instillations at intervals of forty eight hours) Of the forty three monkeys receiving from five to ten intracutaneous injections of vaccine by the multiple puncture method in doses ranging from 0.05 to 0.5 cc per kilogram every five days, thirty-two were found to have acquired effective resistance to intracerebral inoculations of virus It appears that intracutaneous injections engender a higher degree of resistance since doses of 0.1 and 0.25 cc immunized from 80 to 94 per cent of animals, while similar doses by subcutaneous injection immunized from 73 to 75 per cent Paralysis developed in three of the 130 animals This occurred in the 124 animals (in this and a former series) immunized by subcutaneous injections and occurred during the past year when the strain of virus was of greater virulence than in 1934

None of fifty-nine animals given intracutaneous injections showed any evidences of infection during immunization. The intracutaneous administration of the vaccine, therefore, is apparently safer than subcutaneous injections.

Relation of Diabetes to Surgery—While diabetic patients can be prepared for surgical procedures, Abell points out that an increased susceptibility to shock, intolerance to trauma, cardiorenal lesions, lessened recuperative and reparative powers, the ever present threat of acidosis, coexistent arteriosclerotic changes, depletion and dehydration from the effects of starvation, diarrhea and vomiting and the disturbing effect on metabolism exerted by fever and infection combine to make them poor surgical risks. In estimating the surgical risk of a patient with diabetes these problems must be borne in mind, in addition to the immediate surgical condition presented, and further consideration given to complications, hazards peculiar to the abnormal metabolism of diabetes, the effects of insulin and the pathology associated with diabetes. In the presence of surgical emergencies nothing is to be gained by delay in fact, when these possess infection as a feature delay may be actually harmful. The diabetic patients showing the greatest surgical mortality are those in whom complications arise as a result of infection, cellulitis, carbuncles and gangrene.

Use of Sulfanilamide in Treatment of Gonorrhea—Reuter used sulfanilamide in the treatment of 100 cases of gonorrhea in all degrees and stages of infection. Although several patients showed no response to treatment with sulfanilamide so far as the clinical evidence was concerned, they did not show any tendency to get worse and remained stationary. Associated with the administration of sulfanilamide a long list of by-effects were observed, chiefly a profound weakness and fatigue and indescribable epigastric sensations called "indigestion," not associated with nausea or vomiting. Several persons described a sensitiveness of the skin of the lower extremities, and one of these very definitely insisted that there was a marked slowing of and loss of force to the urinary stream. All of these and other minor side-effects disappeared in from twenty-four to forty-eight hours after discontinuance of the agent. Any external or gross evidence of methemoglobinemia or sulfemoglobinemia was not observed. The time of onset of

these symptoms varied, but most patients began to complain when they had taken between 60 and 80 grains (39 to 52 Gm) of the drug. Those who complained early and bitterly of the side-effects gave the best response to the treatment, while the cases which are counted as failures apparently showed a great tolerance for the drug or did not react to it in that yet unknown manner by which it produces its best effect. Of the forty new infection cases treated with sulfanilamide there were three in which the treatment failed. In the old case group of sixty cases, treatment failed in seven. The average length of time for a clinical recovery was five days. In other words, recovery occurred in 92.5 per cent of the fresh cases, and in 88 per cent of the previously treated cases. The treatment consisted of the administration of 40 grains (26 Gm.) of sulfanilamide daily, 10 grains (0.65 Gm.) after each meal and 10 grains at bedtime. The criterion for cure was the disappearance of microscopic pus from the urine, absence of pus from the prostate gland, loss of all symptoms, and the failure to produce a recurrence. It is impossible to say whether or not any of these cases will eventually light up again. Sulfanilamide is well on its way to produce much harm, as well as benefit, unless those who have to do with dispensing it adopt some measures for its control.

*Metabolic Background of Rickets Interpretive Review R Gubner, Brooklyn —p 879
Twenty Five Years of Urology J D Barney and E R Muntz, Brooklyn —p 888

Metabolic Background of Rickets—Gubner defines rickets, as well as osteomalacia, as a derangement of mineral metabolism due to vitamin D deficiency, which is frequently associated with inadequate calcium or phosphorus or both in the diet, leading to characteristic osseous changes. The reduction of serum phosphate and calcium in rickets is due to an inability of the body to hold the normal quantity of these substances, and the action of vitamin D is directly concerned in the preservation of the mineral balance. The conclusion seems warranted that rickets is primarily due to phosphorus deficiency and that lack of vitamin D produces rickets by decreasing the retention of phosphorus, which secondarily depletes the body of calcium. Vitamin D is seen, then to serve as an agency for the conservation of the body's calcium and phosphorus stores, acting to maintain the mineral balance. Depletion of calcium and phosphorus is generally considered to produce rickets by virtue of the serum concentrations being too low to allow calcification to take place. The primary process in rickets, and particularly in osteomalacia, is not defective calcification but decalcification of the shafts of the long bones. The mechanism of decalcification is therefore a basic consideration in the pathogenesis of rickets. It is important that serum calcium and phosphorus be maintained at a certain level, not only to allow effective calcification but to keep a proper concentration of serum calcium, which is necessary for the performance of several other diverse body functions, such as the regulation of muscular excitability and the coagulation of blood. Rickets has thus far been considered as primarily affecting the osseous system. There are, however, important accompanying features, observed clinically, which often overshadow the bony deformities and which have received less attention than is deserved. Thus the rachitic child is often unduly fat, especially in slight or moderate degrees of rickets. Muscular weakness is almost always present, and the prominent symptoms of potbelly and constipation are usually ascribed to atonic abdominal musculature. The muscles are small, very flabby and poorly developed. The effects of muscular weakness are intensified by laxity of the ligaments. The great diminution in serum phosphorus may not be due solely

to its loss through the intestine, the depletion may also be augmented by increased loss through the urine. In all hyperparathyroid conditions, diminution of serum phosphorus with increased urinary phosphorus excretion is a constant finding. The manner in which this increased urinary elimination is accomplished is obscure. Perhaps the following mechanism may operate. The kidney, exclusive of the bones, is the organ richest in phosphatase and an increased phosphatase concentration results in a local hydrolysis of phosphoric esters in the kidney with increased urinary elimination of inorganic phosphate. Whatever the mechanism, the increased urinary phosphorus excretion results in further depletion of the bone forming minerals.

Effect of Acetyl-Beta-Methylcholine on Atonic Colon

—Myerson and his associates discuss the effect of acetyl-beta-methylcholine and its nullification by atropine on the colon of man. In the course of the study it was observed that in well delineated cases of dementia praecox there was frequently a decrease in the tonus and the motility of the colon, which resulted in a delayed emptying time. It was felt that this type of colon was the most suitable in which to observe the effects of the drug. Each individual used in the study received a cleansing enema and two hours later a barium sulfate enema. The dosage was 30 mg of acetyl beta-methylcholine and $\frac{1}{400}$ gram (0.00065 Gm) of atropine sulfate. All drugs were given subcutaneously in the region of the deltoid muscle. Of the forty eight cases of dementia praecox the colon tonus was abnormal in 75 per cent, in 44 per cent it was decreased, and in 56 per cent it was increased. In 71 per cent of the cases the colon motility was abnormal, i. e. decreased. The time required for the emptying of the barium sulfate enema ranged from four to fourteen days. After the injection of acetyl-beta-methylcholine there was marked evidence of an increase in the tonus and in the motility of the colon. As each colon was followed under the fluoroscope there were at first irregularly scattered areas where the tonus would suddenly appear to be increased. These haustrations would frequently disappear entirely, leaving a spastic area from which the barium sulfate would be entirely evacuated. As suddenly as the increased tonus appeared, it would in many instances disappear and there would appear in another place another area of increased tonus. The increased tonus and motility were not confined to any one

specific portion of the colon. They appeared in five minutes, rapidly reaching a maximum of effect at that time and continuing thus for more than an hour, after which the colon appeared to have an increased tonus for at least twenty-four hours. Owing to the increased tonus and motility, during the first thirty minutes the patients would have one or more evacuations, which were imperative and which could not be restrained. The drug did not appear to affect the anal sphincter. At the end of twenty-four hours there had been two, three or four evacuations resulting in a colon that was practically free of barium. In those cases in which both acetyl-beta methylcholine and atropine were administered the atropine was given twenty minutes after the acetyl beta-methylcholine. As the atropine effect would manifest itself, the increased tonus and motility of the acetyl-beta-methylcholine would become definitely lessened and in some instances disappear. Occasionally a definite imperative urge to evacuate would slowly disappear as the atropine became effective. At the end of twenty-four hours the relaxed colon had returned to approximately its original state of tonus and motility.

Diseases Affecting Intervertebral Foramina—The X-ray signs that Oppenheimer presents concern a syndrome of recurrent or persistent pain, discomfort and progressive disability, clinically suggestive of rheumatism, arthritis, or referred symptoms from internal diseases. Segmental neuritis, resulting from compression of nerve roots within the intervertebral foramina, has been shown to be a common cause of these symptoms. In the case of backache and sciatica the correlation with a special type of spinal lesion is well known, but it has not yet been generally recognized that similar diseases in other segments of the spine, as well as pathologic processes of a different origin, may and do produce narrowing of intervertebral foramina and symptoms of segmental neuritis in various regions of the body. As a differentiation of these conditions has been found useful in determining the appropriate treatment, an attempt is made to classify the changes observed roentgenologically that are typical of chronic diseases leading to compression of nerves within the intervertebral foramina. Two groups of diseases, differing distinctly in origin and mechanism, may lead to narrowing of intervertebral foramina. Following the breakdown of tissues which normally support the bones encircling the foramen (1) mechanical collapse occurs, and (2) inflammatory swelling of periarticular tissues, followed by ossifications of membranes and ligaments, will constrict the foramen by encroachment on its lumen. Collapse is produced by softening, rarefaction or loss of elasticity in tissues which normally support the bones that encircle the foramen. Thinning of intervertebral disks (discogenetic disease) and rarefaction of articular processes invariably cause collapse. Constriction is produced by inflammatory swelling of the synovial membranes of the apophysial joint, followed by calcification of ligaments and ankylosis of the facets. The disks are not involved. The correlation of these conditions with hypertrophic spondylitis (deforming spondylosis) and ankylopoietic spondylarthritis is discussed.

Blood Transfusion in Obstetrics—Black speaks of the formation of a blood transfusion service and gives an outline of the indications, method and dangers of blood transfusion. Among the branches of medicine in which there is a place for blood transfusion, obstetrics is preeminent, yet this fact has been neglected for many years on the ground that the pregnant or parturient woman stands the loss of blood better than any other type of patient. One of the greatest needs of an efficient maternity hospital is a blood transfusion service. In June 1936 such a service was started in the Glasgow Royal Maternity and Women's Hospital. Placards had been posted at the entrance to the hospital and in public places in the neighborhood stating that male donors were urgently required and that a fee of £1 and 1 shilling would be paid to any one giving blood. If the heart and lungs were normal and the Wassermann reaction was negative the donor was placed on the roll and informed to that effect. By this means a roll of 180 donors has gradually been built up. All groups are put on the roll. Before a donor is sent for, the recipient's blood is grouped to determine the appropriate donor. The policy of the hospital, notwithstanding, is still to use a relative when possible. By this means a saving of universal donors is effected. When a donor arrives, a rapid direct compatibility test is performed before the transfusion is started. Should a donor be called and not used, he is paid 5 shillings. By means of this service it is hoped to prevent as far as possible deaths from obstetric hemorrhage in the hospital. The main object in obstetrics in giving blood transfusion has been to replace blood loss from hemorrhage. At times it has been given with a view to increasing the patient's resistance to infection. Of the deaths from hemorrhage about three fourths can be prevented by transfusion within one hour of admission to the hospital.

Prevention of Constipation—Dimock claims that constipation is a preventable malady and that the continued use of purgatives is irrational. As constipation is practically unknown among savage tribes, it would appear that a method is required which will overcome the disadvantages of our civilized diets and sedentary occupations. There is now ample experimental evidence showing that the laxative effect of vegetable foodstuffs depends on their "fiber" content. The fiber of green vegetables and ordinary foodstuffs is more readily broken down in the alimentary tract than is that of wheat bran. This explains why the addition of fruit and vegetables to the diet so often fails to prevent constipation. The ingestion of bran and all dietetic measures relying on the action of fiber should be used only for prevention of constipation. The author has used bran as the mainstay of his treatment, combined with the use of a laxative as long as is necessary. Bran should not be added to the diet when constipation is actually present. The bran should be taken daily for a minimal period of four weeks, and as laxation increases the laxative given may be gradually reduced and finally left off. The amount taken varies from one table spoonful to a large cupful. In stubborn cases it may be neces-

sary to give bran twice a day before the patient's usual dose of purgatives can be reduced. The author has not found that the effect of the bran diminishes with use or that more is required, rather there is a tendency for patients to return to normal habits and for less bran to be necessary. Of 121 patients with habitual constipation, 80 per cent were treated with processed bran. The results in 110 cases of simple habitual constipation showed that the treatment was successful in restoring normal habits in 90 per cent, that women were more common sufferers than men in a ratio of 3 to 1, that the menopausal age is the most difficult, and that the prognosis and the rapidity of response to treatment depend on the length of the history of constipation. The psychologic benefit conferred on the patient is contrasted with the outlook of the patient taking laxatives.

Treatment of Urinary Infection—Coombs and his associates state that a normal person can render his urine relatively alkaline or markedly acid merely by suitable selection of his food. Several patients were allowed their own selection of diet, and when no restriction was placed on "acid fruits" such as oranges and lemons it was found that the average pH of the urine was 5.5 or even 6 while the patient received the usual dose of mandelic acid preparations. When the diet was corrected the pH could be maintained below 5.3. The reaction of the urine can be much influenced by the diet both in normal persons and in patients suffering from infections of the urinary tract. It would seem expedient, therefore, to adjust the diet in all cases in which the maintenance of an acid or alkaline urine is of importance. In many cases this control of the diet need not be rigid, slight modifications which are hardly noticed by the patient often being sufficient. It has been found that a strict alkaligenic diet can be taken for long periods without inconvenience. A strict acidogenic diet, however, may sometimes result in slight gastric discomfort, but this, together with the slight dyspnea which often occurs, may be a manifestation of the acidosis and therefore inevitable.

Symptoms of Hepatic Insufficiency in Colitis—Binet

and Baumann state that the gravity of a colitis depends largely on the attitude of the liver If certain inflammations of the colon, no matter how grave, are only temporary it is because the liver has retained its defense properties When these properties have failed, the colitis tends to become chronic The fact that chronic colitis is so rare in children may be taken for a sign that hepatic insufficiency is just as rare The first defense reaction, which makes itself felt in the form of a drastic diarrhea, is directed toward the elimination of septic products This goes together with hyperformation of mucus and bile and comes once or intermittently, mostly in the morning or after meals The resulting irritability constitutes the first attack on the gallbladder One of the principal functions of the liver is the binding of sulfur, which is interfered with in colitis and during which putrefaction and fermentation as also the amount of microbic by-products, are quite considerable It leads to exhaustion of the liver defenses and in course of time the liver is no longer able to conduct correctly the processes of disintegration and synthesis This hyperactivity brings about an increase of the volume of the liver and an intensified indoxyl-emia which may soon return to normal, or it may lead to symptoms of hepatic insufficiency with hyperbilirubinemia and hypercholesterolemia The authors distinguish between early and late hepatic insufficiencies The first may be regarded as a congenital defect of the liver resulting not only from hereditary dispositions like ancestral alcoholism or syphilis it is also found in children with arthritic diathesis who have inherited their functional and organic disturbances These children present a pale or sallow complexion with rings around their eyes listless gaze and a slightly subicteric conjunctiva They are emaciated and remain so in spite of any therapeutic measures owing primarily to their intolerance to many foods Signs of anaphylaxis, such as skin edema, erythema and especially urticaria, appear quite frequently These children suffer much from acetoneuria preceded by stasis at the level of a very vascularized cecum, where an intense resorption of toxic or microbic products takes place this brings to the liver substances which inhibit the normal metabolic decomposition of the acid chains This acetoneuria is also manifested by elimination of acetone bodies in the urine Late hepatic insufficiency occurs in some adolescents but particularly in adults Its crises are frequent in patients with appendicitis operated on or not or typhlocolitis Here too the hepatic insufficiency is never a total one In some patients the biliary excretion is found disturbed, owing to a cholecystitis in which diarrheas alternate with constipation and discoloration with recoloration of stools In others are found anaphylactic symptoms due to impairment of the antitoxic properties of the liver which at times may be aggravated by hemiparesis or glycemia and even

glycosuria but only in exceptional cases In treating hepatic insufficiencies it is therefore necessary to make sure first of possible colitic disturbances before recourse is taken to cholagogues and cholaretics For these the authors recommend hydromineral treatment

Tuberculous Infection of Laboratory Animals and Monkeys—

To prove the efficacy of BCG vaccination in children, Negre and Bretey tested the immunizing power of the smooth types of tubercle bacilli in a large number of guinea-pigs, rabbits and monkeys The bacillus obtained from human pathologic material extracted with acetone grows at 38 C (100.4 F) on glycerinated potato or on egg medium, producing a smooth culture Rabbits were given an intravenous injection of from 10 to 15 mg of the smooth culture bacilli and later an injection of 0.001 mg of virulent bovine culture While these rabbits showed merely rare granulations in lungs and kidneys, the nonimmunized control animals showed numerous tuberculous lesions in these organs The vaccine obtained by the authors proved to be superior in its effects to the BCG vaccine, virulent tubercle bacilli remain for several months in the lymph nodes of the port of entry and do not spread and form progressive lesions, as they do in nonimmunized control animals An intravenous injection of 1 mg of this culture in cynocephalic monkeys brings about an enlargement of the hilar and perihilar shadows with loss of weight, temporary fever and marked development of antibodies Monkeys first immunized by three intravenous injections of smooth colony bacilli and later tested with a subcutaneous inoculation of 0.001 mg of human tubercle bacilli were the only ones that presented no organic lesions as compared with the nonimmunized monkeys which developed a generalized tuberculosis With these experiments the authors believe that they have proved that by repeated immunizing injections it is possible to afford the animal a high degree of protection against experimental tuberculous infection

Bolting or Boring of Neck of Femur—Dreyfus says that for bolting the neck of the femur he uses a simplification of the technic described by Bircher After an S-shaped incision, the neck of the femur is exposed to such an extent that it can be palpated with two fingers Under palpatory and, if possible, visual control, a hole is bored from the trochanter toward the upper half of the head of the femur and a splint of the tibia is introduced in such a manner that, although the base of the femoral head is penetrated, the articular surface is not In boring the hole the author observed that, beginning at the trochanter, boring was at first easy, but that as soon as the borer came near the epiphysal line a severe resistance was encountered After this resistance had been passed, the borer again entered softer tissue The origin of this denser zone, which offers the resistance, is not definitely known as yet, but it has been regarded by Huc as the result of the interruption between the arterial supply of the neck and that of the head of the femur The author himself reasoned that the surgical interruption of this zone would facilitate the development of vascular anastomoses through the opening and, if this was so boring alone should be adequate in some cases He actually produced favorable results simply by boring He cites a number of case histories which prove this In discussing these cases, he adds that the hematoma which develops in the boring canal

is of great significance. Aside from playing a part in the reestablishment of the vascular connection between the neck and the head of the femur, it forms the basis for the structure of the new bone, which considerably increases the supporting power of the neck of the femur. The author points out that in case of detachment of the epiphysis, bolting (after surgical reposition of the head) is a good method for the treatment of *coxa vara*. Boring alone has a favorable effect in not greatly deformed cases. There also are cases in which it is disputable whether boring or bolting is the better method.

Heart Disease Complicating Pregnancy.—Consoli emphasizes the prognostic importance of the myocardial alterations, shown in the electrocardiogram, in cardiac diseases complicating pregnancy. The author followed the behavior of the myocardium during pregnancy and puerperium in 130 women who were suffering from cardiac disease, as well as the evolution of cardiac disease in 175 women including nulliparas and mothers. Pregnancy aggravates heart disturbances and stimulates latent cardiac disease to evolve. At the same time it permits establishment of compensating phenomena by means of which almost all patients tolerate pregnancy and the puerperium fairly well if they are under the care of a physician all through it. The cardiac alterations in course of pregnancy indicate processes of adaptation of the heart to the new humoral, circulatory and nervous conditions created by pregnancy. Decomensation rarely takes place and, if it does, it can be controlled without interrupting the pregnancy, except when the ventricular tonus is disturbed. Persistence of decompensation results in spontaneous production of abortion. Induction of abortion should be reserved only for cases showing grave alterations of the ventricular tonus. The patients have to be taught the advisability of preventing conception because the influence of pregnancy on the evolution of heart diseases is more unfavorable late after the pregnancy is concluded than during its evolution. This is due to the fact that the mechanism of compensation of the heart which is established by pregnancy, ceases when all the biologic and mechanical conditions created by pregnancy are over.

 *Occlusion of Mesenteric Vessels and Intestinal Infarction. A. De Blasi—p. 247

Occlusion of Mesenteric Vessels.—De Blasi studied experimental intestinal infarct from occlusion of the mesenteric vessels. He concludes that the occlusion of the upper mesenteric vessels, either arteries or veins, results in all cases in the production of hemorrhagic infarct. The occlusion of the mesenteric vein and superior mesenteric artery is followed immediately by death. Ligation of jejunal branches of the mesenteric vessels of first and third order is more difficult than that of mesenteric jejunal vessels of the second order. The grave intestinal lesions caused by the occlusion are, as a rule, associated with diffuse lesions of the liver and sometimes also with renal, pancreatic and splenic lesions. The factors which, in association with suppression of circulation, may aggravate the infarct are the type (arterial or venous) and number of the occluded vessels, the caliber of the anastomotic vessels, the duration of the intestinal spasm, the condition of the blood pressure, the time of exteriorization of the intestinal loop out of the abdomen, the reaction of the perivascular nervous plexuses and the amount of bacteria in the intestine at the time of ligation. Care is advised in applying the results of experiments to the interpretation of clinical cases. The entrance of bacteria from the intestine into the blood and the peritoneum

is more frequent in ligation of the arteries than in that of the veins. It depends on the intensity of the intestinal lesion, especially the condition of the intestinal mucosa, the thickness of the enteric wall, the amount of bacteria present, the bactericidal power of the humors of the given animal and the lymphatic lesions caused during ligation of the vessels. Roentgenograms of the thorax of a group of dogs taken some time after induction of the experimental intestinal infarct failed to show the presence of liquid in the abdomen of the animals except in rare cases.

Rare Syndrome from Tumor Within Velum Pendulum.—Simeoni reports a case of mixo-endothelioma within the left part of the velum pendulum, which caused a syndrome of intense somnolence, coughing, dyspnea and cyanosis. The symptoms disappeared after removal of the tumor. According to the author they were caused by compression of the jugular vein and of the vagus nerve by the tumor. The satisfactory results in his case prove the advisability of an early operation. The indications for ligating the external carotid artery on removal of the tumor depend on the size and extension of the tumor. In the author's case, ligation of the external carotid artery was not necessary. Bleeding was not profuse during the operation.

Azotemia and Polypeptidemia After Operation.—Ferracani made determinations of the azotemia and polypeptidemia during the first five days following operations without complications. He found that there is an increase of the polypeptides in the blood after operation which returns to normal after three days. Postoperative hyperazotemia does not show pathologic conditions of the kidney. It shows satisfactory functions of the liver in transforming the proteins and their elimination as urea. The increase of azotemia, followed by decrease of polypeptidemia and azotemia, is a sign of good prognosis. There were no clinically verified complications caused by intoxication with polypeptides in any of the author's cases. The determination of azotemia and polypeptidemia during the postoperative period is the best method of evaluating the behavior of the metabolism of the proteins after operation. It is advisable to complement the determinations with those of chloremia and chloruria. Disturbances of the latter show the need of the organism for rechlorination in the postoperative period.

 Sclerogamous Cholecystitis. E. Vicens and A. C. Molina—p. 231

New Sign for Diagnosis of Diseases of the Breast.—The sign that is described by Benzadon is investigated in the presence of a tumor or inflammation of the breast. It consists in the retraction of the nipple when it is held between the fingers and given a movement of expression at the same time at which the tumor or inflammation is inwardly repelled with the other fingers. The sign is negative when the nipple protrudes and positive when it retracts, taking the aspect of a navel. It is negative in the normal breast and in several pathologic conditions of the breast other than cancer and suppurative galactophoritis. It can be induced early in the development

of cancer, at a time when neither an inflammatory reaction nor the permanent retraction of the nipple has taken place. The author found the sign positive in about forty cases, in all of which the diagnosis was confirmed by an anatomopathologic study.

Formation of New Bone in Organic Nervous Diseases

—Voss points out that the mass experience of the World War demonstrated that traumatic transverse lesions of the spinal cord are often followed by extensive ossifications in the soft parts of the paralyzed limbs. However, such heteroplastic ossifications occur not only after traumatic lesions but also after other spinal, cerebral and peripheral diseases of the nervous system. The author reviews the literature on such cases and then reports four cases which he himself observed. In the first patient ossifications in the soft parts developed after a compression injury of the cauda equina, whereas in the other three cases cerebral hemiplegias of various origins caused the new formation of bone. In discussing the pathogenesis, the author suggests that, in addition to the nervous lesion, other factors must play a part, for, in spite of apparently identical injury or neurologic disease, the ossifications develop in only some of the patients. It has proved impossible so far to produce heteroplastic bone formation in animals by cutting or injuring peripheral nerves.

Enlargement of Sella Turcica of Extrasellar Origin

—Haas says that an enlargement of the sella was formerly regarded as an indication of an intrasellar hypophysial tumor. This caused a large number of incorrect diagnoses. Today, however, it is generally known that an enlargement of the sella does not necessarily indicate a hypophysial tumor, because such an enlargement may be caused also by extrasellar factors. The extrasellar causes may be near the sella and may influence it directly by pressure, or they may be distant and act on it indirectly. In discussing the latter, the author points out that the sella may become impaired by pressure from a secondary hydrocephalic dilatation or by pressure that is exerted by a cerebral tumor. The cause of the dilatation of the sella can usually be determined either by simple roentgenoscopy or by encephalography.

Transfusion of Conserved Blood Plasma in Gynecologic Hemorrhages.—Alovski and Burceva assert that, besides having a substituting effect, blood transfusion also exerts a hemostatic action. The assumption that the hemostatic action was effected chiefly by the plasma was corroborated by investigations. Because plasma can be preserved more successfully and longer than whole blood, it was decided to try conserved blood plasma for hemostasis in gynecologic hemorrhages. On the basis of observations in more than 100 cases, the authors arrived at the following conclusions: 1 The transfusion of blood plasma produces a decided hemostatic effect. 2 The best results are obtained in hemorrhagic metropathia, persisting follicle, menopausal and juvenile hemorrhages. In case of poor hemostasis in the course of operations on the cervix uteri and vagina and in postoperative hemorrhages, the result is like-

wise favorable. In acute inflammatory processes, however, the hemostatic action of transfusion is not so successful. 3 If the first transfusion of plasma fails to produce the desired effect, a second transfusion is frequently successful. 4 The optimal dose is from 40 to 55 cc of plasma. In approximately two thirds of the cases, the transfusion of plasma is followed by a nonspecific protein reaction, but the intensity of this reaction is not dependent on the amount of plasma that has been introduced. The reaction is usually most severe in those cases in which a favorable hemostatic effect is obtained. The plasma is preserved and administered best by means of ampules.

Fluorescence Microscopy of Viruses.—Hagemann describes a new method for the visualization of "subvisible" viruses. In this new method, which he designates as fluorescence microscopy, the virus bodies are stained by means of fluorescing substances, the fluorochromes, in a manner similar to the ordinary methods of staining. Whereas he used berberine sulfate in his fluorescence microscopy of leprosy bacteria (see abstract in THE JOURNAL, June 5, 1937, p 2006), he stained the viruses (canary virus, the virus of infectious ectromelia and the virus of variola vaccine) with a primulin solution. He prepares this fluorochrome solution in the following manner: One gram of primulin is dissolved in 1,000 cc of distilled water and, after 20 cc of liquefied phenol has been added, the mixture is well shaken. If stored in the dark, this mixture can be kept for several days. In order to stain the virus preparations, the primulin solution is poured over them and, after it has acted on the specimen for fifteen seconds, it is washed off with distilled water. The microscope, the general principles of which are described by the author, is equipped with filters which pass only ultraviolet rays. Some experience on the part of the observer is necessary in order to adjust the illumination and magnification to the best advantage. The author concludes that this new method of demonstration of viruses is far superior to all others.

Influence of Coffee on Alcohol Content of Blood and Forensic Value of Alcohol Content of Urine.—Koopmann and Kempfski report studies on the effect of coffee on the alcohol content of the blood. They found that coffee exerts a sobering effect in that the psychic manifestations of alcohol consumption are suppressed after coffee is taken. However, it does not influence the alcohol content of the blood, for the values remain the same or may even increase following the consumption of strong coffee. The alcohol odor of the breath is only temporarily suppressed by the drinking of coffee. The alcohol content of the urine is at first lower than that of the blood, but it increases gradually and finally surpasses that of the blood. This happens whether coffee is taken or not. Regarding the forensic value of the alcohol content of the urine, the authors say that it must be considered together with the alcohol content of the blood, for the examination of the urine, without the simultaneous determination of the alcohol content of the blood, does not permit definite conclusions regarding the degree of drunkenness.

- Role of Hypophysis in Neurology. H. Hoff—p 634

Treatment of Lesions of Ligaments of Knee Joint.—After citing the shortcomings of treatment by means of a plaster cast or by suturing the ligaments, Mandl says that there are many reasons which justify the use of other methods in

the treatment of old ruptures of the crucial ligaments. Since January 1936 he has tried autohemotherapy in patients in whom the function of the knee had not been completely reestablished after a lesion of the ligaments. After disinfection of the knee joint, 20 cc of blood is withdrawn from a vein of the arm. Before this withdrawal of blood, a thin injection needle is introduced subcutaneously in the region of the capsule of the knee joint. By means of this needle the blood is injected fanlike into the capsule. After this injection, which is frequently painful and therefore should be done under anesthesia, the patient should rest for twenty-four hours. After an interval of two days, the injection should be repeated. Observations on approximately fifty patients convinced the author that the results of this method are better than those of surgical repair of the crucial ligaments. If painful points above the articular space indicate a tear or detachment at the insertion of the lateral ligaments, and if symptoms of incarceration are complained of, which prevent normal extension and complete bending, the author resorts to the injection of a 1 per cent solution of procaine hydrochloride. On two or three successive days he injects 5 cc of the solution at the site of attachment of the lateral ligament. He found that this treatment effects complete cure most rapidly. Among those cured were some in whom other treatments had failed.

*Tertiarism in Patients with Paralytic Dementia After Malarial Therapy and Recurrent Fever Therapy A Pilcz—p 577

Track Encephalitis—Hoff and Potzl designate as "track encephalitis" a form of encephalitic processes of the brain stem in the course of which the same route of infection can be recognized, namely, the "trigeminus track," which Doerr and his collaborators demonstrated in infections of the cornea of rabbits with various strains of herpes simplex. Thus the term "track encephalitis" has been patterned after the term "track immunization." The authors apply the term to a group of human encephalitides, which they consider worthy of especial investigation. They cite a case of "track encephalitis," in a child, aged 12. Wallenberg's syndrome was present and since herpes of the cornea had preceded, infection by way of the trigeminus track was regarded as proved. The authors further describe animal tests on the virus. It proved possible to transmit the virus to rabbits. The experiments on the rabbits demonstrated the identity of the chief characteristics of the herpes virus that was obtained from the nasal secretion in a case of "track encephalitis" with the characteristics of the encephalitogenic herpes strains studied by Doerr. However, the examined virus proved exceptional in that the spinal cord was not infectious after encephalitis had been produced by inoculation and that the brain pulp proved noninfectious after myelitis had been induced by means of intravenous inoculation.

Tertiarism After Malarial Therapy and Recurrent Fever Therapy—According to Pilcz, the appearance of symptoms of secondary or tertiary syphilis is extremely rare in untreated cases of dementia paralytica. Moreover, in the few such cases that have been reported the diagnosis is doubtful. On the other hand, in patients with dementia paralytica who have been subjected to fever therapy the casuistics of the syphilitic manifestations on skin, mucosa, internal organs and so on are considerable. The author cites fifty-two cases from the literature, but on account of insufficient data in sixteen cases he evaluates only thirty-six. He shows that among them there was only one case of dementia paralytica in which, after malarial therapy, signs of tertiary syphilis developed and in which the malarial therapy had failed to produce results either as regards the clinical, the serologic or the pathologic-anatomic aspects. In all other cases the classic paralytic symptom complex was somewhat changed, either in that clinical or humoral remissions set in or that the clinical, or even the pathologic-anatomic, aspects were changed. The author concludes that

this summary evaluation supports those theories of the action mechanism of fever therapy which assume a transformation from an anergic into an allergic condition.

Bactericidal Power of Blood—Fajerman reviews recent studies on the Ruge-Phillipp test and stresses that some investigators observed that sodium citrate has an inhibiting effect on the bactericidal power of the blood. In summarizing, he states that the most suitable temperature for setting up blood for a test to determine the bactericidal power is a temperature of about 18 C (64.4 F). The lapse of time between the taking of the blood specimen and the carrying out of the test should not exceed three hours. The addition of sodium citrate in a concentration of 2, 1,000, 1, 1,000 or even 0.5, 1,000 impairs the bactericidal power considerably. This change is brought about mainly by an action of the citrate on the serum. This impairment of the bactericidal power can likewise be observed after the intravenous administration of large doses of sodium citrate. On discussing the clinical significance of these observations, the author points out that in case of immunotransfusion with citrated blood the patient should receive a prophylactic injection of a soluble calcium salt.

*Investigations on Normal Liver Hematopoiesis at End of Fetal Life, at Birth and in Infancy. Contribution to Question of Normal Genesis of Blood Cells A Bertelsen—p 93

Normal Liver Hematopoiesis—Bertelsen's examination of ninety-three premature and full-term children showed a gradual decrease in liver hematopoiesis in the last third of pregnancy, an average of seventeen intralobular blood islands per field of vision with usual magnification still being found at birth, when there are also still a number of myelocytes and diffuse infiltration of erythroblasts in the portal connective tissue. In three normal infants and nine infants who died after acute diseases of brief duration there were also scattered remnants of hematopoietic foci in the liver, from which he concludes that liver hematopoiesis finally ceases after the first year of life and not, as generally stated, at the end of fetal life or directly after birth. In four premature children who lived from eleven days to three months after birth, erythropoiesis was somewhat reduced in comparison to the average for the corresponding stage of development, while the myelopoiesis was rather increased, leading to the assumption that the changes due to birth in the requirements for blood formation in the liver have an especially inhibitory effect on erythropoiesis. The cell values found on differential count of the intralobular blood islands, particularly, are thought to be best explained according to the unitaristic and neo-unitaristic hypotheses concerning the genesis of the blood cells.

PREVENTIVE AND INDUSTRIAL MEDICINE AND PUBLIC HEALTH

NEXT STEPS IN ORGANIZATION AND ADMINISTRATION

CHAIRMAN'S ADDRESS

LEVERETT D. BRISTOL, M.D., DR. P.H.
Health Director American Telephone and Telegraph Company
NEW YORK

Custom and precedent make it possible for the chairman of a section of the American Medical Association to develop his address either from the strictly scientific or from the more philosophic point of view. In choosing the latter course one may assume the role of a historian, describing past or recent trends, a reporter, recording present status, or an amateur prophet, dealing with next steps. In spite of the hazards of attempting to chart the unknown medical "seas" of the future, thirty years' experience, including private practice, the teaching of preventive medicine, the administration of state, county and local health work, and more recently the field of industrial hygiene, have made possible a few brief suggestions as to some of our immediate objectives in the further organization and administration of preventive and industrial medicine and public health.

PREVENTIVE MEDICINE

The dividing line between curative and preventive medicine in the future will be less and less evident, the so-called healing art will become decreasingly pathologic and increasingly physiologic, the clinician and the hygienist will take up arms together in a common cause wherein voluntary and state efforts are more adequately interlocked.

In the field of preventive medicine, the somewhat hesitant steps already taken in some communities to make the doctor's office a real health center and his private practice a focusing point for the modern application of preventive medicine should be strengthened into the firm, sure advance of a well organized program. In this connection there is great need for a community demonstration to bring out the amount and kind of preventive services that should and can be offered successfully by the physician as a part of his regular practice and to determine how best to "sell" the idea of the private practice of preventive medicine to the public so that the doctor's clientele in the future will demand from him and be willing to pay him not only for curative treatment but also for individual health protection and promotion. To this end it is suggested that, with the study, guidance and sponsorship of the American Medical Association and the possi-

ble financial participation of one of the philanthropic foundations, a county medical society demonstration be organized to carry on an active experiment of this nature for a period of five years, the selection of a county society for such a proposed demonstration to be based on (a) a careful, preliminary survey of all county societies that might be interested and (b) the cooperation of associated state and local official and voluntary medical and health societies and boards.

MEDICAL ECONOMICS

Such an organized program of preventive medicine and individual hygiene undoubtedly would point the way to the ultimate solution of the most important health problems of the present day, namely, those insidious scourges of advancing years—diseases of the heart, kidneys and blood vessels, cancer and various nervous and mental instabilities, to say nothing of the ever important communicable diseases. At the same time, such a county medical society demonstration might be so organized as to help answer many questions with reference to the economics of medical care and the responsibility of the public for those unable to provide the medical care they need out of their own resources. The organized medical profession should assume the leadership in the development of a health and medical program which will satisfy the needs and demands of the general public, from the broad aspects of modern sociology and economics.

If majority and minority committee reports on the costs of medical care have been inevitable, how necessary and desirable it would seem to be for majority and minority experiments and demonstrations to be carried on in the field of medical economics! The next five years should be looked on as a period of active trial and critical evaluation of all reasonable plans in the interests of public security against sickness and the conservation of public health, in this connection, the American Medical Association should be prepared to defend its own position and beliefs through a well organized community demonstration, as suggested. Local medical and dental service bureaus for the adjustment and instalment settlement of bills and local associations for the provision of group prepayment of hospital bills are initial steps already taken in several communities toward the more complete coverage of those with smaller incomes who require preventive and curative medical services and more adequate economic security.

INDUSTRIAL MEDICINE

There are at least four steps that might be suggested as desirable in the future development of industrial medicine, and these may be presented briefly as follows.

1. Industrial medicine of the future must place more and more emphasis on prevention, we should think in terms of industrial health. The "company surgeon" undoubtedly will still have a function to perform, in

view of accidental injuries and compensation problems, but "next steps" should involve the more active direction of industrial health programs by physicians well trained in health and preventive medicine, with the assistance of industrial engineers, psychologists, nurses, nutritionists and other personnel that may be required. Mere attention to occupational disease must give way to the active promotion of occupational health. Attention to the prevention of tuberculosis and syphilis and of various types of emotional maladjustment and actual mental disease must become as active in the industrial health program as in the public health program in general, and much of the same methods of control should be inaugurated in cooperation with community authorities.

2 In order to make available well trained industrial health leaders, an important step that must be taken is the better and more general teaching of this subject in our schools of medicine and public health. The growing importance of industrial health would seem to warrant the placing of this branch of instruction under its own independent development in schools of medicine and public health, through a separate department and professorship of industrial health. In a detailed survey I¹ found that only thirteen out of eighty-five medical and public health schools in the United States and Canada give separate courses in industrial hygiene. While a number of other schools assign one or two lectures to this subject in their course on preventive medicine, twenty-one schools apparently give no instruction whatever on industrial hygiene or industrial medicine. There also would seem to be a real need for a cooperative demonstration between local medical schools and industrial organizations in the newer fields of social hygiene and mental health, in order that suitable programs under expert medical guidance may be forthcoming for the benefit of the great mass of the working population.

3 Possibly the most needed step for the further development and administration of industrial health services is the putting into practice of a recently suggested plan² or method for the measurement or appraisal of industrial health and safety activities. A subcommittee on industrial health appraisal of the Committee on Administrative Practice of the American Public Health Association has solicited the wide use of a preliminary trial appraisal form by industrial organizations. As chairman of this subcommittee, I may state that we shall be glad to receive suggestions and recommendations from those who have any practical experience with this tentative form so that, on the basis of group experience, a revised, standardized and official form for the appraisal of industrial health activities may be adopted in the near future.

4 While an appraisal form for the survey and measurement of an industrial health program, as mentioned will be of prime assistance to company management and personnel directors in the development and follow up of their health program, another step that is much needed is the inauguration of a plan by the American Medical Association whereby the quality and quantity of medical services performed in industrial medical departments may be surveyed, measured and possibly approved and

certified. This would seem to be a logical field for the influence and guidance of the entire organized medical profession of the country, which represents, through its association, the work of the general practitioner and all the important specialties.

The rapidly increasing organization of bureaus of industrial hygiene in state and local departments of health during the past year, the passage of laws in several states providing workmen's compensation for certain occupational diseases, the need for defining the functions of health and labor departments as pertain to activities in this field, the questions as to the relative positions of the physician and the engineer in the industrial health program, the proper relationship between industrial medical departments and the private practice of medicine, the better balance between health and safety activities in industry, the problem of how best to furnish much needed industrial health and medical services to the vast number of small business concerns and the constant requirement of improved medical and surgical technic in industry would seem to call for continuous expert thought and advice on the part of the American Medical Association, analogous to that given to medical education and hospital administration in the United States. There is every reason to believe that the management of private industries and various other agencies, official and voluntary, might welcome the guidance of the American Medical Association in things medical, just as have public and private institutions of learning, hospitals and other organizations. The creation of a Council on Industrial Health by the American Medical Association would be a much needed forward step. Representatives of industrial management and labor groups might be invited to serve as consultants or advisers to such a council.

PUBLIC HEALTH

Just as each doctor's office should become a health center for the private practice of preventive medicine so also his office should at least in part become a branch office of the local health department. Only in this way will the public health obstacles of the present and future be overcome. The control of pneumonia, syphilis, mental disease and various other disorders await the more active partnership of private doctor and public health officer. Not until the practicing physician assumes as much obligation and responsibility to the public as he does to his private patient will the problems, which are now pressing for solution, be solved. Moreover, it behooves the private practitioner to go at least half way toward the health department in a spirit of cooperation. In the interest of the better and more complete health and medical care of all the people, the gap in the organized care of the sick must further be closed, the best way to meet the need is for practicing physicians and health authorities to approach one another on the common ground of an active, coordinated program with the financial backing of the public, where necessary.

City health administration of the future must become more and more decentralized, with the possible development of neighborhood health districts and full time district medical officers. Under suitable medical auspices and guidance the city health district plan already in operation in one or two localities could be followed to advantage in many of the large cities. Committee of coordination made up of private physicians and public and voluntary health representatives should be set up for purposes of advisory supervision. Not only

industrial health services, but local city health administration in general, should be closely integrated in the future with the curriculums and courses of local medical and public health schools, so that adequate training centers will be available for the education of prospective physicians and health leaders. Industrial medical departments and city health units should be the practical training and research grounds for the teaching of preventive and industrial medicine, just as are hospital wards for clinical or curative medicine.

While city health administrative units of the future should be contracted and increased in number, rural health units must be expanded and decreased in number. In this development (a) the state department of health, with federal financial assistance where necessary, should assume more authority, through state health districts or bureaus, over rural health administration, or (b) the county should be recognized as the smallest unit for rural health work, or (c) the town health union plan, wherein several small rural communities combine as a unit for health and hospital administration, should be endorsed, based on local conditions and needs. No one pattern for rural health administration seems practicable and feasible for all sections of the United States. The one thing which is evident, however, is that the small town, isolated, part-time, underfinanced local health department, without trained leadership, is entirely out of date, and in many communities there is urgent need for a new model. With available aid from Social Security funds and an increasing interest in rural affairs, the farmer of the future is bound to demand much more and better health protection than he has had in the past.

Whether or not public health degrees, based on special courses in public health, should become prerequisites for appointment to public health positions of leadership is a question that must receive careful consideration in the future. There would seem to be little logic in maintaining highly organized and endowed schools of public health for the granting of such degrees if they are not to be required of specialists in this field.

When better federal, state, local, industrial, collegiate and voluntary health services are built for the benefit of the people of the United States, let us hope that the American medical profession and its representative Association will have a large part in building them.

195 Broadway

ABSTRACT OF DISCUSSION

DR HOLMAN TAYLOR, Fort Worth, Texas. I am delighted to be able to make the report which the chairman requested. The House of Delegates yesterday unanimously approved the idea of a Council on Industrial Health, and the Board of Trustees agreed to set up such a council. The development of such a council will be along the lines of the other councils. I hadn't thought of it so directly before, Texas is not, in the strict sense, an industrial state, and yet there are many industries there. There are the oil industry, gas, and marble and granite quarries. Some time ago our health department established a bureau of industrial hygiene, and a very fine physician was placed in charge. He came to me as secretary of the state medical association for a discussion of his set-up. I asked him to work up his plan of procedure so we could see it, and perhaps prevent any unfortunate repercussions from the practicing physicians or from industry itself. The plan eventually evolved did that.

DR STANLEY NICHOLS, Asbury Park, N. J. It might interest this section to hear of the five year experience we have had in New Jersey with a modification of Dr. Vaughan's plan of organized medical participation. The Medical Society of New

Jersey started, after the White House Conference on Child Health and Protection, five or six years ago, on this program. In developing a program of this sort, the state medical society and the state department of health must get together on common ground and build from that foundation. There have been many approaches to this problem, and some of the functions of the various components in such a public health participation are not yet clearly understood by the family physician. There are two things that a family physician must do. One is that, as an individual physician, he must furnish preventive medical care to all his private patients. That is the fundamental part of this program. Second, as a member of his county and state society and of the American Medical Association he must be ready to furnish medical service to all indigent and low wage groups needing medical service, on terms that are suitable to the organized profession. In New Jersey we are building on that basis and have had the cooperation of the state department of health. The fundamental plan that we have set up is that the doctor, the dentist, the nurse and the medical social worker are projected as the medical service part of a triangle. The second part consists of the official public authorities, whether they are the board of health or the board of education or other public authorities. The third part, and the part that can best "sell" this plan, consists of the lay health agencies, with whom in the past the medical profession had no working relationship. Such a triangle of the administrative groups, the medical service groups and the "salesmen's" groups, the lay agencies, can together do any needed piece of public health work. We have developed, with the help of Social Security funds, our New Jersey plan to preserve the private practice of medicine and to furnish the needed medical service, working together with the public authorities, for the large indigent and low wage group which cannot be carried by the private practitioner any further without assistance. By using Social Security funds, through the close cooperation of our state department of health, we are training our individual doctors both by didactic literature and courses and by using baby health stations, maternal welfare clinics, and tuberculosis and venereal disease clinics as training centers for the practice of preventive medicine by each physician.

LYMPHOCYTIC CHORIOMENINGITIS

DEWITT DOMINICK, M.D.

PHILADELPHIA

In 1936 Scott and Rivers¹ reported two cases of meningitis in man caused by a filtrable virus. The etiologic agent was isolated from the spinal fluids of the patients. The authors pointed out that their serums possessed neutralizing antibodies for at least 100 lethal doses of the virus from nine to eleven weeks after the clinical onset of the disease.

It is the purpose of this paper to report in detail three cases of acute lymphocytic meningitis. Serum taken from the first two patients in this series contained neutralizing antibodies for the virus of lymphocytic choriomeningitis. Serum from the third patient and from a control did not contain such antibodies.

The method employed in proving the presence of the antibodies was in part described by Rivers and Scott² in 1936. It has been modified by Rivers recently and is briefly as follows:

A 10 per cent emulsion of a guinea-pig brain infected with lymphocytic choriomeningitis virus but free from ordinary bacteria is prepared with a diluent of Locke's solution and then centrifugated at full speed for from fifteen to twenty minutes. Serial tenfold dilutions of the supernatant fluid are made with the same diluent, the highest dilution being 10⁻².

From the Medical Service A, the Pennsylvania Hospital.

Dr. Thomas M. Rivers and his staff cooperated in this study.

1. Scott T. F. McN. and Rivers T. M. Meningitis in Man Caused by a Filtrable Virus. I. Two Cases and the Method of Obtaining Virus from Spinal Fluids. J. Exper. Med. 63: 397-414 (March 1) 1936.
2. Rivers T. M. and Scott T. F. McN. Meningitis in Man Caused by a Filtrable Virus. II. Identification of the Etiologic Agent. J. Exper. Med. 63: 415-432 (March) 1936.

0.25 cc of each dilution of virus, ranging from 10^{-1} to 10^{-8} , were mixed with an equal amount of each sample of serum under investigation and allowed to stand at room temperature for five or six hours. All neutralization tests are done with this particular strain of virus in the dilution of 10^{-2} , which is mixed with the various serums to be tested and with known normal serum and homologous immune serum as negative and positive controls. The dilution of the virus is determined on a statistical basis and applied to one particular strain of virus. After suitable incubation, each mixture is inoculated into four guinea-pigs and survival of the four or of three of the four for eighteen days is considered a positive result and the death of the four or of three of the four within that time a negative result.

In the cases reported the serum of the patients was taken for determination of the neutralization reaction approximately forty-three, forty-seven and forty-four days, respectively, after the onset of the disease.

CASE 1—History.—C P, a 14 year old white school girl, who was perfectly well before October 9, 1936, had on that day dizziness, a slight headache (which became worse and confined to the frontal region) generalized muscular pains and stubborn constipation. She went to school but was so dizzy that she was brought home. She remained in bed until her admission to the Pennsylvania Hospital on October 16, approximately the seventh day of the disease. No other members of her family were ill.

Examination.—On admission the temperature (by mouth) was 102.3 F, the pulse rate 116, the respiratory rate 24 and the blood pressure 104 systolic and 80 diastolic. The patient was ill and cranky, complaining bitterly of frontal headache. She held her eyelids nearly closed and the conjunctivae were red, her neck was painful to move but not stiff. The heart, lungs and abdomen were considered normal. The muscles of her legs and arms were painful to moderate finger pressure and painful to move. The neurologic examination gave essentially negative results; there was no Kernig's sign or Brudzinski's sign.

Course.—The temperature went to 104 F and then maintained a course from 104 to 99 F for three days, gradually returning to normal on the twenty-first day of the disease. Headache persisted during this time. Anorexia and constipation were present but improved after the second week. The patient was discharged from the hospital on the thirty-sixth day of the disease apparently well.

A roentgenogram of the chest showed no evidence of tuberculosis. On October 10 there were 11,300 white cells per cubic millimeter and a differential count showed polymorphonuclears

TABLE 1—Data on the Cerebrospinal Fluid in Case 1

Day of Disease	Date	Cells	Differential Count	Initial Pressure Cm of Hg per Water 100 Cc	Chloride Mg per 100 Cc	Sugar Mg per 100 Cc
10th	10/19/36	300	All lymphocytes	200	55	688

114th	1/31/37	5	All lymphocytes	160		

10/20/36—colloidal gold curve 0000000000

52 per cent basophils 3 per cent, lymphocytes 37 per cent, monocytes 1 per cent and Türk's cells 10 per cent. A blood culture on October 17 was negative. Three examinations of the urine and two cultures of the urine for typhoid bacillus had negative results. The Wassermann and Kahn reactions of the blood were negative. The Wassermann reaction of the cerebrospinal fluid was negative on October 20.

The patient was seen on the 114th day after the onset of the disease. She was symptom free, and the physical and neurologic examinations gave negative results. Serum taken on the forty-third day from the onset of the disease contained neutralizing antibodies for the virus of lymphocytic choriomeningitis.

CASE 2—History.—M T, a 19 year old single Polish girl, employed in a dress factory, was perfectly well until October 23,

when frontal headache and dizziness developed. She continued to work that day, but the next two days she remained at home the headache persisting. On the fourth day she returned to work. She was forced to bed on the sixth day more headache, with vomiting and sore throat, having developed. Obstinate constipation was present, and she noticed some stiffness of the neck. She was admitted to the Pennsylvania Hospital on October 31, the eighth day of the disease. There was no family history of infection or illness.

Examination.—The temperature was 100 F, the pulse rate 80, the respiratory rate 24 and the blood pressure 100 systolic and 60 diastolic. On admission the patient was moderately ill and complained of stiff neck and photophobia. Her neck was stiff

11/ 1/36—pellicle acid fast organisms (?)

to lateral motion and painful but not stiff to flexion. The eyes, heart, lungs and abdomen were normal. Neurologic examination gave essentially negative results except for a moderate Kernig's sign on the left. There was no Brudzinski's sign.

Course.—A spinal puncture was done on admission, and because of the presence of cloudy fluid with 1,380 cells per cubic millimeter (which were later believed to be lymphocytes), the patient was given intravenously 30,000 units of anti-meningococcic antitoxin (Parke, Davis & Co.) in 100 cc of saline solution. On the following day, because some doubt was maintained as to the correct diagnosis, an additional 20,000 units of anti-meningococcic antitoxin was given. The patient had urticaria after the second dose of serum.

The symptoms cleared up in approximately five days after admission, the temperature was normal on the fourteenth day of the disease and there was a rise on the twenty-third day to 101 F because of severe rhinopharyngitis. The patient was discharged as well on November 22, the thirtieth day of the disease.

Three examinations of the urine gave negative results. There were 11,100 white blood cells per cubic millimeter on November 2 and 10,000 on November 10. A differential count showed polymorphonuclears 73 per cent, eosinophils 1 per cent, lymphocytes 25 per cent and monocytes 1 per cent. The Wassermann and Kahn reactions of the blood were negative.

Three cerebrospinal fluid cultures were taken, on November 2, 3 and 4, and all were negative. The Wassermann reaction of the cerebrospinal fluid was negative on November 3. Because of the acid-fast organisms (four in all, seen on only one slide) observed on November 2, guinea-pigs were inoculated with the spinal fluid. The results were later reported negative. Spinal fluid sent to Dr. Rivers on the seventeenth day of the disease did not yield a virus. Serum sent to Dr. Rivers on the forty-seventh day of the disease was found to neutralize the virus of lymphocytic choriomeningitis.

This patient was seen on the ninety-ninth day after the onset of the disease. She had gained weight, and the physical and neurologic examinations gave negative results.

A friend of this patient J D, who had no history of illness at the same time or before the patient's illness, was thought to be a good control. He had been in close contact with her before and during the early part of her illness. His serum did not neutralize the virus of lymphocytic choriomeningitis.

CASE 3—History.—C M, a 24 year old white man, married, machinist, was perfectly well until March 15, 1937, when he awoke with headache, nausea and generalized muscular pains. He went to work for two days but was forced to bed on March

17 by aggravation of these symptoms. He had some constipation and noticed that his neck was painful and stiff. He was taken to the Pennsylvania Hospital by ambulance on March 19, the fourth day of the disease. There was no family history of illness.

Examination—The temperature was 103 F (by rectum), the pulse rate 100, the respiratory rate 24 and the blood pressure 120 systolic and 100 diastolic. The patient appeared to be extremely ill, a little irrational and euphoric. He complained of frontal headache and photophobia. His eyes were tender to palpation of the eyeballs, the pupils were equal and reacted to light. The fundus on the right appeared a little blurred on the nasal side of the disk. Examination of the left fundus showed a disk which was blurred and not definitely elevated but a little edematous. The nasal mucosa was slightly red, and some pus was draining from the right ethmoidal region. The other sinuses appeared clear. The pharynx was red, and the tonsils were large and red. The ears were normal. There was some retraction of the neck, with definite rigidity. The heart, lungs and abdomen showed nothing abnormal. The extremities were normal. Neurologically, the deep reflexes were active and equal, there was no clonus or Babinski's sign. Kernig's sign was present on each side. The Oppenheim and Gordon signs were also present. There was no Brudzinski's sign.

Course—A lumbar puncture was performed immediately and after careful search it was believed that a few gram-positive diplococci were seen, although a culture of the spinal fluid was negative. The cell count showed 435 white blood cells per cubic millimeter, which were thought to be polymorphonuclear leukocytes. The patient remained very ill. On the following day, March 20, the spinal fluid contained 1,360 white blood cells per cubic millimeter, thought to be all lymphocytes. Because of suspicion of the presence of diplococci a cisternal puncture was done, and 10 cc of antimeningococcic antitoxin (Mulford's) was injected intracisternally and 20 cc intravenously. A total of 10,000 units of antitoxin was given. On March 21, 10 cc of the antitoxin was introduced into the lumbar region of the spinal canal, and 20 cc was given intravenously. Examination of the eyegrounds showed 1 diopter elevation of the left disk. The patient was given a blood transfusion of 250 cc of blood on March 21 and again the following day, and on the latter day he appeared improved, his headache and general muscular pains gradually decreasing. On March 26, the eleventh day of the disease, severe serum sickness developed, but the patient otherwise was improved. The temperature was approximately 102 F for seven days, with a gradual downward trend to normal on the twenty-first day of the disease. The patient was discharged as well on April 16, thirty-two days from the onset of the disease.

Three examinations of the urine gave negative results. On March 19 a blood count showed red cells 4,450,000, hemoglobin 70 per cent, and white cells 9,000; on March 20, white cells 6,700, polymorphonuclears 87 per cent and lymphocytes 13 per cent; on March 22, white cells 5,000, and on March 29, white cells 7,600. The Wassermann and Kahn reactions of the blood were negative. A blood culture on March 29 was negative. Roentgenographic examination on March 20 revealed that the mastoids were normal, but there was some evidence of sinusitis in the ethmoidal cells, with moderate clouding and thickening of the ethmoidal mucous membranes. On March 24, roentgenographic examination of the chest showed nothing abnormal. No acid-fast organisms were seen in any of four specimens of spinal fluid studied.

Serum was taken from this patient on the forty-fourth day from the onset of the disease and did not contain neutralizing antibodies for the virus of lymphocytic choriomeningitis. The patient was seen on May 18, the sixty-fourth day from the onset of the disease. He had gained weight and was perfectly well.

COMMENT

These three cases illustrate the difficulties encountered in making a correct diagnosis of lymphocytic choriomeningitis. The usual clinical and laboratory procedures are inadequate.

In case 1 the disease was thought to be typhoid fever or tuberculous meningitis until the clinical course and

the positive results of a neutralization test for lymphocytic choriomeningitis definitely ruled out these conditions.

In case 2 the diagnosis was first believed to be meningococcic meningitis. It was thought that on the tenth day of the disease a few acid-fast bacilli were observed in the spinal fluid. No more of these bacilli were seen. Tuberculous meningitis was seriously considered until the clinical course and the positive results of the neutralization test for lymphocytic choriomeningitis proved this to be the wrong diagnosis.

In case 3 the confusion caused by the observation of gram-positive diplococci was evident. The meningitis was later found not to be of the purulent type. The patient's serum did not contain neutralizing antibodies for the virus of lymphocytic choriomeningitis. As in the cases of Shambaugh³ and others, it is possible that the meningitis arose secondarily to infection in the ethmoid sinuses. The exact cause of the pleocytosis will probably remain in doubt.

The three cases fulfilled most of the postulates set down by Wallgren⁴ in 1925 in his description of the disease believed to be aseptic meningitis. They also simulated, particularly in the headache, constipation and

TABLE 3—Data on the Cerebrospinal Fluid in Case 3

Day	Date	Cells	Differential Count	Initial Pressure Cm of Hg per Water 100 Cc	Sugar Mg per 100 Cc	Chlorides Mg per 100 Cc	Cultures
4	3/19/37	435	?	160			Negative

course, the two cases reported by Scott and Rivers¹. All the patients showed persistent and nearly complete lymphocytosis in the spinal fluid.

Clinically, the course of the disease is generally mild. Viets and Warren⁵ in 1937 described severe as compared to mild cases. They reported the death of one patient, who was proved to have encephalitic involvement as well as the usual choriomeningitis. So far as is known, this is the only mortality reported due to this disease. Clinically, the disease is more benign than either tuberculous meningitis or encephalitis. The course is generally short, and recovery is nearly 100 per cent. The neurologic changes when present rarely are localizing. The infectiousness of the disease is still a debatable point.

Reports of observations on the cerebrospinal fluid in cases of lymphocytic choriomeningitis indicate that the sugar content is between 40 and 70 mg and the chlorides about 700 mg or less per hundred cubic centimeters. Predominant lymphocytosis should always be present. According to Viets and Warren,⁵ the protein content in severe cases usually has a tendency to rise.

To make and prove the correct diagnosis of this disease, the virus should be isolated from the spinal fluid. How late the virus can be observed is not definitely known. It apparently disappears soon after the tenth day. According to Rivers and Scott,² neutralizing antibodies cannot be seen in the serum until after

the sixth week from the onset of the disease. Because of the possible confusion with other forms of meningitis, it seems of great importance that if the virus is not obtained from the spinal fluid the serum should be tested for neutralizing antibodies.

That lymphocytic meningitis may be caused by etiologic agents other than this virus was demonstrated by Rivers and Scott.² They failed to find neutralizing antibodies against the lymphocytic choriomeningitis virus in the serums collected from seventeen patients who had recovered from diseases diagnosed as acute aseptic meningitis and from five patients convalescent from lymphocytic meningitis of unknown origin.

The term lymphocytic choriomeningitis should be employed in cases of lymphocytic meningitis only when the organism is found, or when the neutralization tests of the serum have positive results.

SUMMARY AND CONCLUSIONS

Of three cases of lymphocytic meningitis, two were later proved to be lymphocytic choriomeningitis.

It is possible for lymphocytic choriomeningitis to be confused with meningitis caused by other etiologic agents.

It is important to demonstrate the presence of the virus in the spinal fluid early in the course of the disease or the presence of neutralizing antibodies in the serum after the sixth week.

A NEW METHOD OF PREPARING INFUSION FLUIDS

BASED ON REMOVAL OF PYROGEN BY FILTRATION

CO TUI, M.D.

K. L. McCLOSKEY, M.D.

MILTON SCHRIFT, M.S.

AND

A. L. YATES

NEW YORK

A better understanding of the physiology of body fluids has led to universal intravenous use of dextrose solution and physiologic solution of sodium chloride. There is hardly a medical specialty that can dispense with their use. While most infusion fluids may be said to be safe, occasionally a febrile reaction, or series of reactions, occurs. The factors alleged to cause these reactions are mostly conjectures, which have accumulated in the way of clinical traditions until the preparation of infusion fluids has become so cumbersome that many hospitals now resort to commercially prepared fluids, some Council accepted and some not. This has imposed an added financial burden on hospitals. At the same time most of the factors alleged to be causative of this reaction have not been thoroughly investigated.

REVIEW OF THE LITERATURE

"Reactions" following the intravenous injection of aqueous solutions have been known nearly as long as intravenous therapy itself. These reactions are characterized by fever, often chills, vomiting, and other gastro-intestinal disturbances. The fever begins from

thirty to forty-five minutes after injection, reaches its height in from two to four hours and then begins to recede, until it has fallen practically to normal in from four to six hours. In our work there is also found a leukopenia within the first forty-five minutes after injection.

The literature on the subject was reviewed by Seibert¹ in 1923. Up to that time the only definitive work was that of Wechselsmann² and of Hort and Penfold.³ Wechselsmann in 1911 showed that febrile reactions following the intravenous administration of arsphenamine solutions could be eliminated if the solutions were made with distilled, germ-free water. This disproved the theory that the reactions were a specific water or salt effect. Hort and Penfold in the same year found that water obtained by distillation from a Jena glass retort did not produce fever if injected at once. However, a sample of the same water allowed to stand in an unsterile vessel at room temperature for forty-eight hours produced marked fever. They further showed that there was no parallelism between the toxicity of water and the number of microorganisms present and that the "pyrogen" was in the supernatant portion of a centrifugated specimen and was filtrable through a Doulton filter, cotton wool and even a Berkefeld filter. Seibert¹ extended this work, identified a bacterium from distilled waters standing in nonsterile containers, showed that the pyrogen was the product of this organism but not the bacterial bodies themselves, and that it was not retained by Berkefeld filters. She further showed that water distilled from an all-pyrex still equipped with a spray catching trap and used within twenty-four hours was nonpyrogenic. Bourn and Seibert⁴ subsequently identified two groups of river bacteria causative of this febrile reaction. They were groups X and XI of Jordan, the latter group causing a milder reaction than the former. This work was confirmed by Banks⁵ in 1934. Rademaker⁶ in 1930 stated that he confirmed Seibert's work and formulated a set of rules governing the preparation of infusion fluids. Perkins⁷ and recently Walter⁸ reported that infusion fluids prepared according to the specifications of Rademaker are nonreactive. It may be said that at present fluids are prepared according to the specifications of Seibert and Rademaker in most hospitals and commercial houses.

However, reactions still occur. While in the case of hospital-prepared fluids such accidents may be attributed to the oversight of an overworked staff, for fluids prepared in commercial houses, where occasionally pyrogenic samples are encountered, there is no such excuse. Here mechanized and standardized methods of production are in use.

An analysis of the method recommended by Seibert and Rademaker shows its weakness. Most emphasis

Aided by a grant from the Works Progress Administration. The ultrafilter was lent us by the Pfaltz & Bauer Company, New York. From the Laboratory of Experimental Surgery, New York University College of Medicine. The authors were assisted by Dr. Benjamin Shafiroff and given encouragement and advice by Prof. Arthur M. Wright.

is laid on the distilled water and the purity of the chemicals, but no remedy is recommended for possible contamination during the preparation. The method may be summarized in this schema

Distillation → addition of chemicals → sterilization

Thus while the distilled water and the chemicals may be of unquestioned purity initially, there is no insurance against contamination during the latter part of the preparation, i. e., during the addition of chemicals and subsequent handling. A redistillation is out of the question, and Berkefeld filtration does not hold back the pyrogen, once it is present.⁹

In this communication we are presenting a new method of preparing intravenous fluids. It is based on

for forty-eight hours and (2) a markedly turbid water from a fresh water aquarium used in the laboratory. The water was boiled and filtered through hard filter paper, and sodium chloride was added to make a physiologic solution. It was then reesterilized in the autoclave before injection. It may here be mentioned that the normal temperature of dogs ranges from 100.6 to 102.6 F.

In this study a number of precautions were necessary. They were occasioned by the fact that, as previously mentioned, in clinical circles, in addition to the presence of pyrogen in infusion fluids, it has been alleged that a number of other factors cause febrile reactions. The precautions pertinent to this investiga-

the new principle of pyrogen removal by a special type of filtration. This principle was worked out in an extensive investigation of infusion fluids known to be pyrogenic.

In our filtration studies of proved pyrogenic fluids we employed the following types of filter: (1) Jena filter crucible, (2) Berkefeld filter W, (3) Zsigmondy membrane ultrafilters of graded porosity and (4) Seitz serum No 3 filter pads¹⁰ made of compressed asbestos.

Table 1 embodies a study made on dogs, a preliminary communication of which has been published.¹⁰ The pyrogenic infusion fluids were made from two lots of water: (1) tap water from the city main incubated

tion were (a) the pH of the fluid,¹¹ (b) contamination by the rubber tubing through which the fluid is administered,¹² (c) the temperature of the injected fluid¹³ and (d) the speed of the injection.¹⁴

Accordingly, the pH of the fluid was taken before and after filtration, the rubber tubings used were 2 foot lengths of gum tubing which had previously been used

⁹ Seibert¹, Hort and Penfold.²
¹⁰ Owing to an error in labeling these filter pads were called Seitz EK filters in our preliminary communication (Co Tui, McCloskey, K L Schrift, M H, and Yates A L, Filtration Studies on Reactive Infusion Fluids, Proc Soc Exper Biol & Med 35: 297-300 [Nov.] 1936).

repeatedly for other infusions and were thoroughly rinsed with sterile distilled water and autoclaved before each use, the fluid was maintained at 39 C throughout the injection, the speed of injection was in each case regulated by gravity or gravity plus air pressure to 0.5 cc per kilogram of body weight per minute, i.e., the equivalent of 900 cc every thirty minutes for a man weighing 60 Kg. The temperatures were taken at half-hour intervals for a period of five hours. Only two leukocyte counts were made as a rule, one before and the other forty-five minutes after injection.

Experiments 1 and 2 are the controls. It will be seen that 45 cc of the aquarium water produced more of a reaction than 130 cc of the tap water. Experiments 3 and 4, show that neither a Jena filter crucible nor a Berkefeld W filter, the finest obtainable, removes the febrile agent. This result confirms the observations of Hort and Penfold³ and of Seibert.¹ Filtration through a Seitz serum pad No. 3 removes it, however, as may be seen in experiments 5 and 6. Since Seitz filters act by adsorption, it is concluded that the pyrogen is adsorbable. Experiments 7 to 11 are attempts to determine the particle size of the pyrogen. Since it passes through a 42-second filter but is held back by a 200-second filter, it is concluded that the particles are larger than 50 millimicrons.¹⁵ A more exact study is now being made on the particle size by more precise methods of ultrafiltration.

Table 2 embodies five series of representative experiments on men out of a series of thirty-two pyrogenic fluids investigated. Twelve of these thirty-two were fluids made by local hospitals and fourteen were commercial fluids made by three manufacturers, all Council accepted, the rest were made in our own laboratory.

The first series dealt with a commercial 5 per cent dextrose in saline solution. This preparation is described by the manufacturer as "a solution containing in each 100 cc 5 Gm of anhydrous dextrose and 0.85 Gm of sodium chloride." The protocol of L. L. was taken from the hospital record. It will be seen that the temperature after the intravenous injection rose from 100.6 to 105.6 F and that the leukocyte count fell in forty-five minutes from 11,500 to 900. Five hundred cubic centimeters of the same fluid filtered through two Seitz serum No. 3 asbestos pads gave no fever in volunteer M. C. Series II deals with another batch of 5 per cent dextrose in saline solution which was biologically tested and rejected as pyrogenic by the same commercial house and submitted to this laboratory for investigation. Volunteer L. T. responded to an intravenous injection of 250 cc of this fluid by a temperature of 102.6 F. Four hundred cubic centimeters of the same solution was given to an 11 Kg dog, resulting in a marked temperature rise and leukopenia. One thousand cubic centimeters of the same fluid filtered through a 200-second Zsigmondy membrane filter gave no reaction to the patient. Through one layer of Seitz serum No. 3 filter, 600 cc still gave a slight fever but 1,000 cc after filtration through two layers of Seitz filter pads was followed by no rise in temperature.

Series III was performed with a commercial 10 per cent dextrose solution from another manufacturer. This solution labeled 10 per cent "dextrose solution" is described in the label as "a sterile solution of dextrose-glucose 10% in physiological saline." Series IV and V were saline solution and aquarium water used on the dogs in table 2. The toxicity of the aquarium water is shown in the experiment in which 40 cc in a human

being (A. P.) gave a temperature of 103.8 F and a fall of the leukocyte count of from 10,000 to 5,000. The lack of reaction when 1,000 cc each of the filtrate of the same water is injected after filtration through a 200-second Zsigmondy and through a Seitz serum No. 3 filter attests the high efficiency of these methods of filtration and confirms the observations made in dogs.

The leukopenia accompanying this reaction is invariably present in dogs, as may be seen in table 1, but less constant in human beings, although when the reaction is marked it is unmistakable, as in series I, in which the drop in the count reached a level as low as 900. This is a transient phenomenon, most marked in the first hour or two, with restoration to normal in a few hours. This phenomenon will be the primary subject of a subsequent study.

It will be seen from the p_H values recorded in tables 1 and 2 that they range from p_H 4.10 to 7.88 for reactive fluids and from 5.61 to 7.52 for nonreactive fluids. Under these conditions, then, the p_H value per se cannot be the cause of the reactions caused by these fluids.

COMMENT

The theoretical implication of this work is that the pyrogen found in infusion fluids is of a particulate nature, of a larger order of magnitude than 50 millimicrons but smaller than 1 micron. Whether it is of protein or of other composition, whether it acts as a particle per se or in some other way and whether other particulate substances of this dimension can reproduce this phenomenology remain to be investigated. This finding is not necessarily at variance with Seibert's. It is easily conceivable that the products of the "bacillus pyrogenes" could occur as particles of this size.

The practical result of this work is that there are now available two processes of filtration which effectively remove the reactive agent from infusion fluids. One is ultrafiltration, which, however useful it may be in the determination of particle size, is too slow and technically too difficult for clinical use. The other process is adsorptive filtration through two layers of Seitz serum No. 3 filter pads (compressed asbestos). This process is easy to manipulate and should be feasible for use in hospitals and commercial houses. The adsorptive filtration is really the core of the process, since neither distillation of the water nor a final sterilization by heat is essential, although both are recommended. The former, because on general principles it is best to use water free of chemicals other than those prescribed, the latter, to avoid bacterial contamination during bottling. This new process of infusion fluid preparation may be summarized by the schema

Distillation → addition of chemicals → adsorptive
filtration → sterilization

SUMMARY

In a study with infusion fluids known to be fever producing, it was shown that

1 The fever-producing agent is removable by filtration through an adsorptive filter and through a 200-second Zsigmondy filter.

2 The agent is of a particulate nature of a larger order of magnitude than 50 millimicrons but smaller than 1 micron.

3 A new method of infusion fluid preparation consists of passing the final fluid mixture through compressed asbestos filters of the Seitz serum No. 3 type.

THE VISUAL RAVAGES OF
TRACHOMA

HARRY S GRADLE, MD

CHICAGO
AND

WALTER DE FRANCOIS, MD

HARRISBURG, ILL

While the ravages and destructive influence of trachoma are well known, it would be difficult to say offhand how great percentally is the visual damage from that disease and how much that damage can be remedied by treatment. Therefore this analysis was made of the records of 2,713 consecutive cases of trachoma seen in the Southern Illinois Trachoma Clinics to answer that question. The U S Public Health Service¹ estimates that 4 per cent of patients with trachoma in any given community are blind. MacCallan² gives the statistics on the visual acuity of the inhabitants of the village of Bahtim. Forty-eight per cent of the 1,301 trachomatous individuals measured had vision of less than 6/18, while 5.5 per cent were blind in one eye and only 1 per cent blind in both eyes. The standard of blindness was the inability to count fingers at less than 1 meter. But, says MacCallan, "The causes of blindness in the great majority of cases were the results of acute conjunctivitis and ulceration of the cornea. There were many cases of primary glaucoma causing blindness and a comparatively small number of cases in which trachoma was the only cause without the help of acute conjunctivitis." More accurate figures are not available.

The patients in the series here reported were divided into several classes according to visual acuity for specific reasons. It is well known that ability to read fine type requires visual acuity of 20/50 at least. Consequently, vision of less than 20/50 implies difficulty in near vision. According to the definitions accepted by the American Medical Association in 1935, less than 20/200 constitutes industrial blindness. Thus there are clearly defined limits for the various classes which may be discussed under the following sections. It must be added that corrected vision was utilized when available, but, as these clinics are only for the treatment of trachoma in indigent patients, refractions could not be performed and the majority of glasses that were in the possession of patients were of the "five and ten cent store" variety. But every patient was examined ophthalmoscopically and the refractive error estimated roughly. Any complicating factors that could have an influence on the vision were noted and we were thus able to state definitely whether or not the decreased visual acuity was due to trachoma and its complications.

A Vision better than 20/50. In the total number of 2,713 patients there were seventeen with unilateral anophthalmos from one cause or another. Therefore we are dealing with 5,409 eyes. Of that number 2,889, or 53.5 per cent, had visual acuity of better than 20/50 and consequently are not considered in this article.

B Vision between 20/50 and 20/200. Of the total number of 5,409 eyes 1,596, or 29.5 per cent, had visual acuity between 20/50 and 20/200. The reduction in

vision was due to trachoma in 653 of that number, or 40.9 per cent. Under treatment, 250, or 39.8 per cent, improved to vision of better than 20/50.

C Vision less than 20/200. Of the total number of 5,409 eyes 924, or 17.0 per cent, had vision of less than 20/200. The reduction in vision was due to trachoma in 566, or 61.1 per cent. Under treatment, 177, or 31.2 per cent, improved to vision of better than 20/200.

D So far we have spoken of individual eyes so now let us speak of patients. Of the 2,713 patients 211, or 7.8 per cent, had suffered a reduction in vision in the better eye as the result of trachoma to less than 20/200 (industrial blindness). Under treatment fifty-five, or 26.1 per cent, of that number improved to vision of better than 20/200.

It is fully realized that these figures are not universally applicable, for trachoma varies in severity in various localities according to the character of the population and the degree of sanitation, according to the climate, the temperature, and the amount of humidity, and above all according to that indefinite factor known as racial resistance. The patients in these clinics are Caucasians who have been more or less inbred for more than a century, who are mostly country dwellers, and whose ideas of sanitation are very rudimentary.

SUMMARY

1 In the Trachoma Clinics of Southern Illinois, 7.8 per cent of the patients are industrially blind as the result of trachoma and its complications.

2 More than one fourth of these can be restored to useful vision by treatment.

3 Of the individual trachomatous eyes, about 30 per cent have a reduction in vision that interferes with satisfactory reading, about two fifths of the reduction being due to trachoma.

4 Of the individual trachomatous eyes, 17 per cent are industrially blind, about three fifths of the reduction being due to trachoma.

5 Vision can be restored to the useful point in from one fourth to one third of the eyes, the percentage varying according to the degree of loss and the length of time it has existed.

58 East Washington Street

ABSTRACT OF DISCUSSION

DR C E RICE, Washington, D C. Two years ago I visited some of these trachoma clinics in southern Illinois. Dr Gradle is to be congratulated on the way this work has been organized. It is a fine example of a public health enterprise. In a study of 1,600 case records of trachoma patients hospitalized in Missouri, it was found that there were 82 blind eyes to each hundred cases of trachoma. That would figure out slightly more than 4 per cent of the patients blind if the two eyes were always affected to the same degree. Fortunately, that is not always true. These blind eyes were those with light perception. Of about 4,000 case records studied (not all patients hospitalized) there were 12.5 per cent with vision of 20/200 or less in the better eye, due to trachoma. Dr Gradle found 8 per cent of the patients with vision of 20/200 or less because of trachoma. It is of much interest that in Dr Gradle's study it was found that approximately one fourth of those persons blind from trachoma could have useful vision restored by proper treatment. The earliest case of severe trachoma I have seen was in a baby of 18 months. Pannus had already involved the greater part of both corneas. In this case, a bilateral canthotomy and grattage was done following two months of hospital care. The final result was excellent. This case is cited to illustrate that trachoma can be very severe early

From the Governor Horner Trachoma Clinics of Southern Illinois. Read before the Section on Ophthalmology at the Eighty Eighth Annual Session of the American Medical Association, Atlantic City, N J, June 9, 1937.

in life. Another interesting point is that trachoma can remain unilateral. I have seen twelve patients with unilateral involvement to the extent that one eye of each patient was blind, while the other eye had normal visual acuity and no sign of a previous trachomatous infection. In Egypt it would appear that most of the blindness in trachoma sufferers may be due to complicating gonococcal infections of the conjunctiva. This is not true in the endemic trachoma area of this country. Trachoma produces blindness because of the transfer of the disease process or infection to the corneal tissue. This transfer occurs early. As to whether economic blindness will occur in the untreated case depends on the factors of (1) virulence of the infection and (2) individual resistance, and, as the authors say, there are apparently racial factors and possibly geographic factors.

GAS GANGRENE TREATED WITH SULFANILAMIDE

REPORT OF THREE CASES

HAROLD R. BOHLMAN, M.D.

Instructor in Orthopedic Surgery, Johns Hopkins University
School of Medicine
BALTIMORE

Search of the literature fails to reveal the use of sulfanilamide¹ heretofore in the treatment of gas gangrene. It appears to be a valuable adjunct in this respect and offers great promise with regard to saving of limb and life.

CASE 1—W. C., a Negro youth aged 15, admitted to Franklin Square Hospital Jan. 12, 1937, after being struck by an automobile while roller skating, suffered mild shock and concussion, a transverse fracture of the right femur in the mid third, and a compound fracture of the left femur in the lower third which extended longitudinally through the metaphysis and involved the outer half of the epiphyseal cartilage plate, the proximal fragment protruded through the lateral surface of the thigh above the knee. The wound area was treated, the compound fracture was reduced, dressings of dry gauze were applied, and both fractures were splinted, 1,500 units of tetanus antitoxin plus 10,000 units of combined gas bacillus antitoxin were given. His temperature rose to 102 F on the second day and fluctuated in an irregular manner.

When I saw him on the fifth day after injury his left leg was very much swollen, it was well splinted with a temporary arrangement, as was the right. Palpation of the right thigh revealed no abnormal swelling. He complained of pain in the left leg and when the dry, blood-stained dressings were removed, gas escaped with a loud hiss and continued to bubble from the wound, giving off a somewhat pungent odor. Gas crepitation could be felt over the lower part of the leg from 4 inches above the ankle, about the knee, and up the thigh to within 3 inches of the groin. This distention with gas had occurred with great rapidity—literally over night. The wound was discharging hemolyzed blood and necrotic material. There was no frank pus. The patient looked very ill. He was restless, talkative and apprehensive, with lapsing moments of quiet which suggested marked toxicity. The pulse was 140, temperature 101, respiration 24, leukocyte count 17,500.

A spica plaster splint was applied about the body, right hip and leg, holding the femoral fragments in good position. Hasty presurgical preparation was carried out, and nitrous oxide and oxygen were administered. An incision was made from just below the greater trochanter down the outer side of the left leg through the skin, subcutaneous tissue, and tensor fasciae femoris, extended through the wound site, where much necrotic material was encountered, and down the lower part of the leg to just above the ankle. In this long, widely gaping wound, only about twelve clamps and ties were necessary to

control hemorrhage. The tissues were edematous and pale with practically no capillary oozing. Scattered indiscriminately about the wound were four sharply delineated areas, each roughly 2 inches long by 1½ inches wide of black, gangrenous tissue. Crepitation persisted over much of the leg. No attempt at debridement was made. The long, wide wound was dressed with loosely applied gauze saturated with hydrogen peroxide and protected with petrolatum gauze. The patient was under anesthesia a very short time and then returned to his bed, where sand bags were used to fix the leg. Because of the great distention, extensive infection and the patient's toxicity, amputation seemed to offer little hope. His prognosis was very poor.

Sulfanilamide therapy was immediately instituted. Long suggested a dose of three tablets of 5 grains (0.3 Gm.) each every six hours. This dose was continued for two days, followed by two tablets every six hours for five days and then one tablet every three hours for an additional two days. Eighteen hours after the first dose of sulfanilamide the patient's temperature was normal, he had no toxic symptoms and he appeared quite well.

Excellent union occurred in the right femur. His general condition has remained good, there have been no subsequent toxic symptoms. The black, necrotic, gangrenous areas softened, sloughed, and were expelled in masses resembling dirty putty. The long, wide wound was allowed to granulate and epithelize. A low grade osteomyelitis subsequently developed, which is responding very well to treatment. A sequestrum of a portion of the metaphysis has been removed, union is excellent. At times, when dressings have been too infrequent or drainage not entirely free, he has exhibited a slight rise of temperature. At operation, smears of the wound revealed immense numbers of gas bacilli, morphologically *B. welchii*, also a few cocci in chains and tetrads. The laboratory reported only *Staphylococcus aureus* in culture, failing to obtain either streptococcus or gas bacillus growth.²

CASE 2—A. C., a Negro aged 42, was admitted to the same institution March 21, 1937, after being struck by an automobile. Aside from sundry bruises and contusions, he sustained extensive multiple, comminuted fractures of the left tibia and fibula, with similar injuries to the right lower leg and a compound wound about 1 inch by 2½ inches over the upper, anterior third of the tibia. Considerable soft tissue crushing and damage was evident, with no air or gas palpable in either leg. The patient was given a prophylactic dose of tetanus antitoxin and combined gas bacillus antitoxin.

His temperature on the third day was 100.4 F, with a pulse rate of 95, marked crepitation of gas could be felt about and above the wound, extending to the lateral side of the knee. The wound was discharging hemolyzed blood. The leukocyte count was 12,000.

Sulfanilamide therapy was started, five tablets every four hours. The patient received 25 grains (1.6 Gm.) the third day (the first day of this therapy), 75 grains (5 Gm.) the fourth day, 30 grains (2 Gm.) the fifth day and 45 grains (3 Gm.) the sixth day, after which it was discontinued.

His temperature ranged from normal to 99 plus until the tenth day and thereafter was normal. All toxic symptoms disappeared on the fourth day, that is, the second day of sulfanilamide therapy. The wound was not disturbed. One felt that he had sufficient drainage from the wide open compound wound, and after the experience with sulfanilamide in the first case it seemed worth while to depend on it entirely in this much earlier stage of gas gangrene.

Recovery was complicated by staphylococcal osteomyelitis of the upper end of the right tibia, which is responding to treatment.

No organisms were found on culture of the wound on the third day. This may have been due to much hemorrhage occurring before the culture was made. However, there was a sufficient quantity of gas in the tissues to warrant a presumptive diagnosis of infection with gas bacilli.

CASE 3—Miss M. C., aged 21 years, white, admitted to Union Memorial Hospital in a severe state of shock at 3:45 a. m. May 8, 1937, had been injured in an elevator accident in a hotel.

Physical examination revealed ecchymosis of the right eye, bruises and contusions of the arms, right breast and right thigh.

Dr. Perrin H. Long of the Johns Hopkins Hospital and Drs. T. Battaglia, S. S. Borssuck, M. J. Sodara and W. F. Feidler of the house staff of the Franklin Square Hospital cooperated in the treatment and care of cases 1 and 2 and Dr. Arthur J. Weinberg treated case 3.

2 Long, Perrin H. Personal communication to the author.
3 Momentary difficulties in the laboratory prevented proper culture.

laceration of the right scapula, and a compound comminuted fracture of the lower third of the right femur with severe crushing of the soft tissues. As soon as her condition warranted, she was taken to the operating room and a guillotine amputation of the right leg was done under cyclopropane anesthesia at the upper third of the thigh, after thorough clean-up with green soap, physiologic solution of sodium chloride and iodine, the wound of the shoulder was sutured. Amputation was performed above the fracture area, the stump was closed in the usual manner with two cigaret drains. She was immediately given prophylactic doses of tetanus antitoxin and combined gas bacillus antitoxin.

Her temperature on admission was 99.3, rose to 102.2 the second day, and was 103.3 the third day, with a pulse of 140 per minute. A culture of the wound revealed *B. welchii*. The leukocyte count was 18,000. Hemoglobin was 70 per cent.

Sulfanilamide was administered four tablets of 5 grains (0.3 Gm.) each with 10 grains (0.65 Gm.) of sodium bicarbonate every four hours totaling 60 grains (4 Gm.) the first day, 85 grains (5.5 Gm.) the second day, 65 grains (4.3 Gm.) the third day, 40 grains (2.6 Gm.) the fourth day, 60 grains (4 Gm.) the fifth day and 40 grains (2.6 Gm.) the sixth day, after which it was discontinued. Her temperature remained elevated until the seventh day, when it dropped to 98 and ranged to 99.5, being normal after the twenty-fifth day. Her pulse remained around 100 to the minute. X-ray examination of the stump on the second day revealed gas pockets. The urine on the second day showed albumin 2 plus sugar 1 plus and numerous hyaline casts but thereafter was normal.

Quantitative determination of sulfanilamide in the blood on the fourth day revealed 8.4 mg. per hundred cubic centimeters.

As soon as gas bacilli were discovered in the discharge on the second day, the sutures in the stump were removed, there has been some necrosis and sloughing. The wound is at present granulating and the patient is progressing well toward complete recovery.

Marked clinical improvement was noted in all three cases, especially cases 1 and 3 within twenty-four hours after sulfanilamide therapy was instituted.

SULFANILAMIDE

Borssuck⁴ first called my attention to the use of sulfanilamide and to the work of Domagk,⁵ who demonstrated its selective action on streptococcal infection in mice.

Long and Bliss⁶ called attention to the clinical value of sulfanilamide in a preliminary report and later made further observations,⁷ which included the proper dosage for oral administration. They suggest decreasing rapidly the amount of chemical administered following prompt improvement, with a longer period of administration in a mild, chronic infection. They note that toxic manifestations are apparently infrequent and may be associated with sulfhemoglobinemia, they reiterate the chemotherapeutic effect of this chemical in the treatment of infections produced by beta hemolytic streptococci.

I have used this product in such cases and in mixed infections of streptococci and hemolytic staphylococci, also in one case of *Staphylococcus aureus* infection, all with excellent results.

Marshall, Emerson and Cutting⁸ have reported on the excretion of this chemical and they comment that the mechanism of its action is not yet clear, that the curative effect is exerted by maintaining a high concentration in the blood and tissues for several days, that adequate

concentration can be as quickly obtained by oral administration as by injection, and they note various factors influencing concentration. They suggest that the daily dose be divided in order to maintain as nearly uniform concentration in blood and tissues as possible. A four hour interval between doses is indicated, and they suggest a large single initial dose. They state that no advantage is gained by subcutaneous injections as compared to oral administration. They found that by establishing equilibrium between intake and output nearly 100 per cent of the drug was recovered from the urine. Excretion is slowed by impaired renal function and they suggest caution in cases of this type.

GAS GANGRENE

The literature is replete with articles on various phases of gas gangrene and anaerobic infection. Many authors call attention to the incidence of gas gangrene in compound fractures. Ghormley⁹ calls attention to the value of antitoxin. In my experience it has been extremely disappointing. Each of my three patients received prophylactic doses of 10,000 units of combined gas antitoxin. Ghormley also calls attention to the mixed type of infection often present in these wounds.

Millar¹⁰ lists a series of 607 cases occurring in civil life, not including obstetric infections, in which *B. welchii* was associated with streptococci and staphylococci in six, with cocci in three and with miscellaneous bacteria in nineteen. He remarks that gas gangrene is not listed as a cause of death in the Bureau of Census mortality tables of the registration area in the continental United States.

The surgeon general's¹¹ report calls attention to symbiosis of various aerobes and anaerobes. In Base Hospital No. 15, A. E. F., in seventy-three cases of gas gangrene with death, activity of the gas bacilli was self limiting and practically confined to the first week after the wound was received, with a drop in anaerobes from 38 to 7 per cent during the first seven days, as the common pyogens streptococcus and staphylococcus accumulated rapidly in the wound. The symbiotic effect was particularly prominent in fatal wounds. Infections with anaerobes alone showed a high death rate but a short period of danger to life. A streptococcal bacteremia was by far the most important cause of death, especially in patients living beyond the first week, which was roughly established as a self-limiting period of gangrenous process and "many deaths attributed to the anaerobes were in reality deaths due to streptococcus in the process of replacing them." In Evacuation Hospital No. 8, A. E. F., between Sept. 10 and Nov. 13, 1918, 4,741 wounded were admitted to the hospital. Of these, 4,683 required surgical treatment, 206 of the wounded required amputation, and of the 206, ninety-six, or 46.6 per cent, were for gas gangrene. The total number of deaths was 363, of which sixty-one, or 17 per cent, were due to gas gangrene, the second most important cause of death. "Of 890 wound cultures 478, or 53 per cent, contained anaerobic bacilli. Of these 478 wounds, 321, or 67 per cent, at no time showed clinical evidence of gas gangrene infection.

Of the remainder of the gas gangrene cases, sixteen, or 3 per cent, developed gas gangrene after debridement, while in 141 cases, or 29 per cent, gas gangrene was clinically evident at the time the wound culture

¹⁰ Millar, W. M. *Surg., Gynec. & Obst.* 54: 232 (Feb.) 1932.

¹¹ Surgeon General's Report. U. S. Army. 12: 407, 1929.

was made. It is thus seen that more than two thirds of the severe, nontransportable wounds contaminated by anaerobic bacilli failed to develop gangrene, all of these cases being under observation at least five days, and many of them as long as two weeks. This fact involves a very important pathological principle. These bacteria are incapable of producing gas gangrene by their presence alone and must be accompanied by the failure of circulation, the extensive cellular damage of large quantities of muscle, and in all probability by constantly progressive increase of this series of factors."

Experimentally, injection of large quantities of washed *B. welchii* failed to produce lesions in laboratory animals, but lesions would develop if either acid or powdered glass was injected with the bacilli or if slight injury to the muscles preceded the injection. "In other words, the Welch bacillus is not a true parasite but a saprophyte that cannot grow in healthy tissue, it is able to thrive only if the body cells are first injured by some chemical or mechanical means. The lesions involve the muscles, the blood vessels, and the fat of the subcutaneous connective tissues."

Ghormley⁹ gives 42.5 per cent mortality, slightly lower than 53 per cent recorded in the surgeon general's report.¹¹ He states that 86 per cent of a series of thirty-three patients recovered with the use of antitoxin. Prophylactic dosage of combined gas bacillus antitoxin did not prevent infection in the three cases now reported. Millar¹⁰ found a mortality of 47.2 per cent, recovery in 48 per cent, and unknown outcome in 48 per cent in 607 cases.

Long¹² is at present conducting experiments with *B. welchii* to determine the effect of sulfanilamide on their growth and phagocytosis. He believes that phagocytosis is not inhibited or enhanced by this drug, that it acts directly to inhibit the growth or multiplication of these bacilli and that its mechanism of action on other bacteria is similar. He states that a prophylactic effect has been noted whenever it has been used therapeutically in experimentation. He suggests that prophylactic doses of two to three tablets every four hours with 10 grains of sodium bicarbonate be given in all severe or crushing injuries in which infection with streptococci or gas bacilli might subsequently occur.

Mellon, Gross and Cooper¹³ find that sulfanilamide does not affect phagocytosis or change the histologic response to streptococcal infections in mice.

SUMMARY

- 1 The first case represents an amazing, not to say dramatic, result in a desperate case of gas gangrene. Cases 2 and 3 are confirmatory.
- 2 Sensible, conservative surgical principles should be combined with the use of sulfanilamide.
- 3 No previous record has been found of its employment in this manner.
- 4 I am convinced it will be of great value in saving limb and life.
- 5 Sulfanilamide probably has a specific effect on gas bacilli, but the results may in part be due to checking symbiotic growth with the streptococcus.
- 6 The problem should have further study and experimentation.

THE COMPARATIVE VALUE OF PURINE DERIVATIVES IN THE TREATMENT OF ANGINA PECTORIS

MORTON G. BROWN, M.D.
AND
JOSEPH E. F. RISEMAN, M.D.
BOSTON

During recent years theophylline with ethylenediamine (aminophylline) has enjoyed considerable popularity in the treatment of angina pectoris. This drug was introduced in 1908 by Dessauer¹ as a preparation which was more soluble, more effective and less likely to produce nausea than theophylline. More recently theophylline and theobromine have been linked chemically with other compounds in an attempt to imitate and improve on the properties of aminophylline. Each of these drugs has been used in angina pectoris with good results. Unfortunately, however, little exact information is available concerning the relative merits of these purine derivatives.

The available reports are based on clinical experience with the drugs.² It has been shown³ that clinical evaluation alone gives a false impression as to the efficacy of treatment in angina, for the administration of even inert medication may be followed by clinical improvement. The purpose of the present investigation is to determine the comparative efficacy of caffeine, theobromine and theophylline derivatives in the treatment of angina pectoris by using the usual clinical methods and also by measuring the amount of work under standardized conditions which patients can perform before heart pain develops.

METHODS

A detailed plan of the investigation has been published in previous communications.⁴ For the purpose of this investigation, seventeen patients who showed definite improvement following one or more of the purine derivatives were selected. So far as could be determined, they suffered from no disease other than coronary arteriosclerosis. The clinical course and the amount of work under standardized conditions which they could perform before cardiac pain developed were well known in each instance.

Each drug was given four times a day for one week at the end of which time the exercise tolerance and

This study was aided by a grant from the DeLamar Mobile Research Fund of the Harvard Medical School.

From the Medical Research Department of the Beth Israel Hospital and the Department of Medicine, Harvard Medical School.

The following pharmaceutical houses gave generous supplies of their products: Abbott Laboratories, theophylline with methyl glucamine; Bilbuler Knoll Corporation, theobromine with calcium salicylate and theophylline with calcium salicylate; Eli Lilly & Co., theophylline mono-ethanolamine and theophylline mono-ethanolamine with amylal; Winthrop Chemical Co., Inc., theobromine with phenobarbital and theophylline with sodium acetate.

the frequency of attacks during the preceding week were determined independently by two observers. When there was evidence that the medication had benefited the patient, tablets of sodium bicarbonate were substituted until the effect of the specific medication disappeared. At a later date the efficacy of the effective medication was again determined without the patient's knowledge.

Because of occasional spontaneous changes in the clinical condition of the patients⁵ it was impossible to administer every drug to each of the seventeen patients. Seven of the eleven preparations were used in from fifteen to seventeen cases, four were used in from eleven to thirteen cases.

In general the amount of work under standardized conditions which a patient with angina pectoris can do is an accurate index of the response to therapy and affords a means of checking the clinical impression. Medication that resulted in an increase in exercise tolerance of 50 per cent or more usually caused a striking diminution or complete absence of attacks in daily life. An increase of 20 per cent or less was accompanied by little or no clinical improvement obvious to the patient. For the purposes of simplicity in presentation, therefore, the results are presented in terms of increase in exercise tolerance.

TABLE 1—The Effect of Increasing the Dosage of Purine

Dose 4 Times Daily Grains	Patients Benefited per Cent	Frequency of Gastric Distress per Cent
Theophylline		
2	33	13
3	54	13
4	33	33
Theophylline with calcium salicylate		
4	46	0
8	67	27
12	43	86*

* In half of these patients the discomfort was so severe that they discontinued the medication.

The optimum dosage of each drug was determined by measuring the increase in exercise tolerance following different dosages and also by ascertaining the frequency of gastric distress.

RESULTS

The Optimum Dosage—In general the frequency and degree of improvement increased as the dosage was increased. All theobromine and theophylline derivatives, however, caused nausea or heartburn when given in sufficiently large amounts, and when this gastric distress became severe any improvement which had been induced by smaller doses disappeared. The optimum dosage for most patients was the maximum amount that could be given without causing severe gastric distress (table 1), in a few instances, however, equally satisfactory improvement could be obtained with somewhat smaller doses.

There is reason to believe that the available preparations are loose chemical mixtures. The soluble preparations probably break down in the stomach to give the free purine and the chemical compound which has been added to make the preparation more soluble. It is not surprising to find, therefore, that both the beneficial effects and the gastric distress increase roughly in proportion to the amount of theobromine or theophylline present in the doses administered. The calcium

salicylate mixtures are less soluble, larger doses of theobromine or theophylline can be given before gastric distress becomes evident.

Theophylline Derivatives—Six theophylline preparations were used. Two were relatively insoluble (theophylline, 3 grains [0.2 Gm.] and theophylline with

TABLE 2—The Comparative Value and Cost of Purine Derivatives

† Great improvement.

‡ The cost of these preparations is based on the prices published in the catalogues of the pharmaceutical houses.

§ These represent the cost per thousand doses of the medication in tablet or capsule form as prepared by the pharmaceutical houses. All other costs are based on the price per pound of powder plus the cost of manufacturing tablets.

calcium salicylate, 8 grains [0.5 Gm.]), the remaining four were more soluble (theophylline with sodium acetate 2½ grains [0.15 Gm.], theophylline with ethylenediamine 3 grains, theophylline mono-ethanolamine 3 grains, theophylline with methylglucamine 2½ grains [0.14 Gm.]). The most effective preparation was theophylline with sodium acetate (table 2). Patients who did not respond to this drug usually showed a good response to theophylline with calcium salicylate, which was the second best preparation.

The theophylline content of the effective dosages varied from 1½ to 3½ grains (0.08 to 0.25 Gm.). The effective dosage of theophylline with ethylenediamine and that of theophylline mono-ethanolamine apparently

TABLE 3—The Effect of Combining a Sedative with a Purine

Preparation and Dosage*	Patients Benefited per Cent	Frequency of Untoward Effects per Cent
A Theobromine 5 grains	31	6
Theobromine (5 grains) and phenobarbital (½ grain)	40	20
B Theophylline mono-ethanolamine 1½ grains	54	9
Theophylline mono-ethanolamine (3 grains) and amylal (¾ grain)	60	10

* All preparations were given four times daily.

† Theominal (Winthrop Chemical Co. Inc.).

‡ Theamin (Eli Lilly & Co.).

depended in large measure on the theophylline content. The addition of sodium acetate and methyl glucamine apparently enhanced the effect of theophylline, whereas the addition of calcium salicylate allowed more theophylline to be administered before gastric distress became evident.

Calcium salicylate and ethylenediamine hydrochloride were each administered to ten patients, in no instance was there any evidence of beneficial effect.

Theobromine Preparations—Theobromine with sodium acetate has received insufficient attention in the past. This drug in doses of $7\frac{1}{2}$ grains (0.5 Gm.) four times a day was far superior to all other preparations of theobromine and was as effective as the best of the theophylline compounds. Theobromine with calcium salicylate (15 grains [1 Gm.]) was also of considerable value and about equal to theophylline with ethylenediamine or theophylline. Theobromine 5 grains (0.35 Gm.) and theobromine with sodium salicylate $7\frac{1}{2}$ grains gave almost identical results and were distinctly less effective than other preparations (table 2).

Caffeine Derivatives—Caffeine citrate was the only preparation used. The drug is apparently of little value in angina pectoris, for only one patient showed questionable benefit from its use. No patient had more attacks while taking this drug, although clinical experience has shown that in an occasional individual pain may develop on drinking coffee.

Combinations of Sedatives with Purines—Two preparations were used, theobromine with phenobarbital (theominal) and theophylline mono-ethanolamine with amytal (theamin and amytal). The amount of work that patients could do after taking these preparations was essentially the same as after the use of the purine derivative without the added sedative (table 3). From the practical standpoint the use of sedatives is of distinct value in the treatment of angina pectoris, for it makes the pain easier to bear. It is inadvisable, however, to combine the two drugs in a single tablet or capsule, for the optimum dosage of each ingredient varies for different patients.

COST OF MEDICATION

In most patients the benefits of purine medication disappear soon after the drug is omitted. It is necessary therefore to administer the preparations for long periods and at least three or four times a day. Under such circumstances the cost of medication becomes an important factor. Theobromine with sodium acetate is the least expensive of the effective purine preparations. For hospital use the powder can be purchased from chemical houses in 5 pound lots⁶ and made into tablets resulting in a cost of approximately 16 cents for one week's supply (thirty doses) as compared to a cost of from 60 cents to \$1.14 for other preparations. In our experience the cost of 100 capsules of theobromine with sodium acetate on prescription usually retails for considerably less than other preparations.

SUMMARY AND CONCLUSIONS

1 The comparative value of six theophylline, four theobromine and one caffeine preparation in the treatment of angina pectoris was determined in seventeen patients by using the usual clinical methods and also by measuring the amount of work under standardized conditions which could be done before inducing heart pain.

2 The optimum dosage was usually the maximum amount that could be given without causing severe gastric distress.

3 Not all patients respond to purines. The sodium acetate derivatives of theophylline and theobromine were the most effective preparations. Patients who did not respond to these drugs usually showed a good response to theophylline with calcium salicylate, which was the next best preparation.

Theophylline, theophylline with ethylenediamine, theophylline mono-ethanolamine, theophylline with methyl glucamine and theobromine with calcium salicylate were about equally effective but were less so than the aforementioned preparations.

Theobromine and theobromine with sodium salicylate were distinctly less effective, while caffeine citrate was of little or no value.

4 Sedatives are of value in the treatment of patients with angina pectoris, but their combination with a purine does not result in an increased exercise tolerance.

5 Theobromine with sodium acetate is by far the least expensive of the effective purine preparations.

TULAREMIA, PULMONIC FORM

REPORT OF FOUR RECOVERIES

MALCOLM D. WINTER, MD

MILES CITY, MONT.

BROWNLOW C. FARRAND, MD

JORDAN, MONT.

AND

HARRY J. HERMAN, MD

JERSEYVILLE, ILL.

It has been only fifteen years since Edward Francis¹ described tularemia, a new disease in man. Since that time it has been widely recognized in all parts of the country. The ulceroglandular form is quite common in eastern Montana where the wood tick *Dermacentor andersoni* and the jack rabbit are prevalent. We see relatively few cases due to the skinning of rabbits, since they are little used for food in this locality. Most of our cases are associated with tick bite or occur in the handling of tick-infested sheep. The incidence of infection varies greatly and seems to coincide with the rise and fall of the jack rabbit population. An epizootic of tularemia among the rabbits seems to kill off most of them and there is relative freedom from human tularemia for a few years until it develops in a new generation of rabbits.

The present report is based on a group of cases, all seen in the spring of 1933 during the lambing season. All were associated with handling sheep and with tick bites. It was thought that the unusually wet spring made the handling of the sheep more hazardous and that they were most likely due to contact with tick excreta in the wet wool. In none of these patients was there any history or sign of primary ulcer or glandular involvement.

REPORT OF CASES

CASE 1—*Tularemia pneumonia with meningitis*. D. C. F., aged 35, a sheep man, of excellent habits, married, the father of two children who are alive and well, had always been well except for a six months stay in a sanatorium in Scotland in 1907 for suspected pulmonary tuberculosis. No positive diagnosis was made. He had acute appendicitis and an appendectomy in 1926. He also was ill for a few days with mild influenza in 1932.

He went to a sheep camp for lambing operations May 1, 1933. During the following week he was exposed to much cold wet weather and loss of sleep. Rain made it necessary to handle most of the sheep. They were all moderately infested with both the sheep tick *Melophagus ovinus* and the wood tick *Dermacentor andersoni*. As is the custom, he skinned dead lambs.

Dr. Herman died April 15.
Assistance was rendered by the technician and staff of Holy Rosary Hospital.
¹ Francis Edward, Tularemia, a New Disease in Man. J. A. M. A. 78: 1015 (April 8) 1922.

⁶ The theobromine with sodium acetate used in this study was purchased from Merck & Co.

and tied the skins on the backs of orphan lambs that their foster mothers would own them. I am told that tularemia in sheep may cause stillbirths, hence these lambs may have been the source of his infection. He was bitten by a tick May 5. This occurred on the forehead and was not followed by any ulcerous or glandular involvement. He became ill May 10 at which time he had a shaking chill, high temperature, general aching and drenching sweats. He was seen by one of us on the third day of his illness and was thought to have influenza. He continued to do badly, however, severe pleuritic pain in the left side of the chest, bloody sputum and signs of beginning consolidation in the left apex developed on the sixth day of his illness. He was admitted to the hospital the next morning with a temperature of 104 F (40 C), pulse 110 and respirations 30.

On physical examination the patient was obviously very ill with anxious facies and grunting respiration. There was no mark or ulcer at the site of the tick bite or elsewhere. The lymph glands were nowhere enlarged or tender. The eyes, ears, nose and throat were normal. The expansion of the chest was limited on the left. The heart was not enlarged, and the heart tones were moderately rapid but of good quality. There were no murmurs. The blood pressure was 110 systolic, 80 diastolic. The lungs showed beginning dulness at the left apex with pleural friction in the left axilla. The breath sounds were

markedly somnolent. The tremor had become so bad that he could not hold anything in his hands and definite rigidity of the neck was noted for the first time. A lumbar puncture revealed a turbid spinal fluid with some increase in pressure. The cell count of this fluid was 670, globulin one plus, differential lymphocytes 96 per cent, polymorphonuclears 4 per cent. A fibrin web formed on standing. No organisms could be found. The spinal fluid sugar was 0.008 gram per hundred cubic centimeters. The Wassermann reaction was negative. The colloidal gold curve was 1122343000. We then did a daily spinal drainage for five days with marked clinical improvement. The cell count falling on successive days as follows: 500, 300, 232, 120, 60, 15. On this basis we made a diagnosis of meningo-encephalitis.

When first seen because of his exposure to ticks, blood was taken for tularemia tests. It was reported negative for tularemia May 18, the eighteenth day of illness, as well as negative for typhoid and undulant fever. A second test taken ten days later was reported by Dr Francis of the National Institute of Public Health as follows: Tularemia was positive by complete agglutination in dilutions of 1:160 and partial in dilutions of 1:320. Cross agglutination with *Brucella abortus* was present but serum was classed as tularemia by the agglutination absorption test and by the more rapid agglutination of *Bacterium tularensis*. A third test June 9 was identical. The urine remained

Fig. 1 (case 1)—Appearance (A) on admission showing involvement of the left upper lobe (B) fifteenth hospital day showing partial resolution of the left upper lobe and involvement of the right middle lobe (C) thirtieth hospital day showing complete resolution.

bronchovesicular at the left apex where there were many crackling rales. The abdomen was distended and tympanic. The spleen could not be felt though there was some tenderness in this region. The reflexes were negative. The neck was not stiff and there was no Kernig sign. Examination of the urine was negative and the white blood cell count was 8,150. X-ray examination of the chest showed a bandlike area of consolidation at the left apex (fig. 1A).

His temperature fell by lysis for the first three hospital days, then rose again as an irregular intermittent type, ranging from 99 to 105 for fifteen days, then falling by lysis reaching normal on the twenty-third day and remaining so until discharge (fig. 2). His pulse at first was relatively slow in relation to his temperature until the eleventh day, varying from 80 to 110 and later going as high as 136. It remained elevated to from 100 to 120 for two weeks following a normal temperature. The blood pressure remained low throughout the disease and the pulse was distinctly dicrotic. Pneumonia extended rather slowly, involving the greater portion of the left upper lobe and a portion of the right middle lobe (fig. 1B). The sputum was intermittently bloody with a slight odor until the twentieth day of the disease. Resolution also was very slow and the lungs, which were checked frequently by X-ray examination, were not reported as practically clear until the thirtieth day (fig. 1C).

On the twentieth day of the disease we noted that he seemed drowsy and had a rather marked coarse tremor of the hands. This became more marked and made it necessary to catheterize and feed him. The blood urea taken at this time was 75 mg per hundred cubic centimeters. Five days later there was more

normal throughout the course of the disease except for an occasional small amount of protein. The white blood cell count varied between 5,600 and 10,750, tending to rise late in the illness. The Schilling count, May 31, was as follows: band forms 18 per cent, segmented forms 47 per cent, lymphocytes 31 per cent, eosinophils 1 per cent, monocytes 3 per cent. The sputum was repeatedly negative for acid-fast bacilli. Inoculation of it into a guinea-pig done when the patient was practically well was negative. From the meningo-encephalitis he made a slow but rather uneventful recovery. He left the hospital on the thirty-ninth day of illness and when next seen September 1, had gained 20 pounds (9 Kg). He still, however, felt weak and noted palpitation of the heart and some dyspnea on exertion. He has continued to gain in strength and in January was only slightly dyspneic. X-ray examination of the chest was negative.

CASE 2—Tularemia pneumoniae ophthalmi stomatidis. J. E. P., a farmer, aged 37, married, of good habits was admitted to the hospital May 27, 1933, ten days after the admission of the first patient. His condition so closely simulated the first case that little difficulty was experienced in diagnosing it.

The patient's past health had always been good. The family history was negative for cancer and tuberculosis. He gave a history of having been bitten by ticks under the left arm and in the left groin twenty-four days previous to his admission to the hospital. A week later he became ill with high fever, cough and marked general aching. He was seen by another physician who thought he had influenza. He continued to feel

bad staying in bed most of the time. During this time headache and tinnitus were very troublesome. His temperature was apparently quite irregular, though no records were kept. He was first seen by us on his admission to the hospital. He had been ill seventeen days and was complaining of pain in the right side of the chest, which was worse when he breathed. He was extremely weak and dizzy. He coughed frequently, raising

Fig. 2—Temperature and pulse in case 1

a tenacious bloody sputum with slight odor. The temperature was 103.4 F (39.6 C), pulse 110, respiration rate 32. The eyes, ears, nose and throat were normal except for moderate pyorrhea and moderate deafness, which he said was made worse by his illness. The latter was of the conduction type. There was no evidence of tick bite, nor were any of the superficial lymph glands enlarged. The chest was emphysematous in type. The lungs showed dullness on percussion over the left upper and right middle lobes. The breath sounds over these areas were bronchovesicular and there were many moist rales. The

reported positive for tularemia in dilutions of 1:1,280 and negative for undulant fever. The urine remained normal except for an occasional trace of protein. The sputum was repeatedly negative for acid-fast bacilli. June 13 a marked aphthous stomatitis developed, which gave him considerable trouble for about a week. Guinea-pig inoculation of the sputum June 17 was negative. He was discharged, July 10, after a stay of forty-four days in the hospital. A roentgenogram of the chest taken a few days before dismissal still showed considerable involvement (fig. 3C) even though the pulse and temperature had been normal for ten days. After returning home he continued to gain slowly, except for a fever of six days duration that forced him to stay in bed. He was last seen in the office on August 14, when he was feeling fine, though still weak. He had gained 20 pounds (9 Kg). An x-ray film taken on this date showed almost complete clearing except for a rather marked fibrosis over the areas that had been involved.

CASE 3—Tularemia pneumonia. D. O., a white man, aged 50, single, a sheep herder, admitted to the hospital May 5, 1933, complained of pain in the chest, headache, loss of appetite and strength and moderate cough. He stated that he had been well until a week before admission, at which time headache, malaise and general aching developed and he thought he had the 'flu'. He had no chill but felt feverish. After two days he was forced to go to bed. He was alone in the sheep camp and had to care for himself. He had been bitten by ticks several times in the preceding weeks but none of the bites festered or gave any trouble, and he had not noticed any swollen glands.

The patient was well developed and weighed 175 pounds (79 Kg). His face was flushed and he seemed dull and apathetic. There was occasional coughing, with scanty tenacious sputum. The temperature was 101 F (38.3 C), pulse 90, respiration rate 18. The tongue was clean and moist. The tonsils were not enlarged. The neck was flexible. The thyroid was not palpable. There were no enlarged glands. The heart was not enlarged. There were no murmurs. The blood pressure was 110 systolic, 80 diastolic. The lungs were resonant throughout on percussion. At the right base the breath sounds were

Fig. 3 (case 2)—Appearance (A) on admission the seventeenth day of illness showing extensive involvement of the left upper and right middle lobe (B) thirtieth day of illness (C) on discharge the sixty-second day of illness

heart was not enlarged; its tones were of good quality and there were no murmurs. The blood pressure was 110 systolic, 80 diastolic. The abdomen was soft. The spleen was not palpable or tender. The reflexes and sensations were reported as normal.

X-ray films of the chest showed a picture very similar to that of the previous patient. Figure 3 shows quite well the evolution of the pneumonia. As will be noted by the dates of the pictures, his condition changed very slowly. While never so desperately ill as patient 1, he was ill longer. Figure 4 shows the temperature and pulse curves.

The white blood cell count taken May 27 was 9,000 and again on June 18 it was 8,950. The Schilling count was small lymphocytes 22 per cent, segmented forms 31 per cent, band forms 38 per cent, eosinophils 3 per cent, juveniles 6 per cent. Blood taken on the day of his admission to the hospital was

increased but not definitely tubular. Over this area there were many moist rales. The abdomen was distended and tympanic and there was slight generalized tenderness throughout. The reflexes were physiologic and there was no stiff neck or Kernig sign. Careful inspection of the skin showed no ulceration or marks from tick bite, and the lymph glands were nowhere enlarged. The white blood cell count was 10,800. The urine was normal.

The patient remained in the hospital from May 5 to June 1. During the first two weeks of his stay he had an irregular temperature varying from 101 F (38.3 C) to 104 F (40 C), the pulse ranging between 90 and 110 and the respiration rate from 18 to 38. The area at the right base developed slowly until definite consolidation with pleural friction was present. No x-ray films were taken. After two weeks he slowly improved.

Because of the atypical course of the pneumonia and the history of possible exposure to tularemia, blood was sent to the Montana State Board of Health and was reported positive for tularemia in dilutions of 1 320

After discharge from the hospital, he gradually gained strength but when last seen, two months later still felt a bit weak and a little breathless on exertion

CASE 4—*Tularemic bronchitis with small pleural effusion*
L H, a man aged 31, single, a rancher regarded himself as perfectly well until the onset of his present illness His family history was negative for tuberculosis His personal habits were good He gave a history of pneumonia in childhood and again in 1927

Fig 4—Temperature and pulse in case 2

He had been caring for sheep during the lambing season and stated that he had been bitten by ticks almost daily removing from four to five from his body each day since March 28 Some of these bites festered a little but there was no definite ulcer anywhere nor had he noted any enlarged or tender glands He began to feel weak and lame May 10 but continued to work until the 18th, when he felt feverish and had a bad headache During this time he had had a severe cough with streaks of

Scattered through both bases were many dry and whistling rales, especially on coughing These seemed more numerous on the right A friction rub could not be detected The heart was not enlarged and there were no murmurs The blood pressure was 112 systolic 84 diastolic The abdomen was scaphoid There was no tenderness and the spleen could not be felt There was evidence of an old compression fracture of the first lumbar vertebra The reflexes were normal X-ray films of the chest showed increased bronchial markings on the right with a small amount of pleural effusion (fig 5) The white blood cell count was 6,500 and the urine was normal Blood taken May 29 was positive for tularemia in dilutions of 1 160 and negative

Fig 5 (case 4)—Tularemic bronchitis with pleural effusion

for undulant fever A second sample taken June 9 was reported by Dr Francis of the National Institute of Health as follows positive agglutination for *B tularensis* in a dilution of 1 320, positive for *Brucella abortus* in a dilution of 1 320 The serum was classed as tularemia because of faster agglutination and because of the agglutinin absorption test

He remained in the hospital only four days During his hospital stay, the temperature fell to about 100 F and was normal when he was discharged

In a month the patient was well

COMMENT

A search of the literature reveals only twenty patients who have recovered from tularemic pneu-

blood in the sputum, which was scanty There was slight pain in the right axilla on breathing

On examination the patient was moderately ill, with frequent cough and marked weakness The temperature was 101.2 F, pulse 96 respiration rate 20 The tonsils had been cleanly removed The eyes, nose and throat were otherwise normal The chest expansion was limited on the right The lungs were resonant throughout except at the right base where there was a narrow band of flatness The breath sounds were vesicular

monia We add the records of three more, one of which was complicated by involvement of the central nervous system This complication has resulted in a fatal outcome in all the previous reports that we have seen

The treatment received by these patients was largely symptomatic with the addition of intravenous injections twice a day of sodium salicylate 12 Gm, dissolved in

30 cc of distilled water. Whether this therapy had anything to do with our mortality we are not prepared to say, but it was our impression that this measure seemed to make our patients less toxic.

In case 1, daily spinal drainage was carried out after meningeal symptoms developed until the spinal fluid was clear. This measure we feel sure was definitely beneficial. After each tap the patient became mentally much more alert.

Dyspnea on exertion and general weakness predominated for some months after recovery and would lead one to believe that a toxic myocarditis was the usual sequela.

Our experience as to the frequency of clinical pulmonary involvement in ulceroglandular tularemia does not coincide with that of Blackford,² as pulmonary complications were not present in any of our cases of the ulceroglandular type, nor was either ulcer or glandular involvement present in any of our pulmonic cases.

We do feel that the portal of entry in these cases was most likely through the skin, although it is possible that the patients may have eaten food contaminated by the fingers, the damp wet weather making inhalation of infected material very unlikely.

Any atypical pneumonia with a relatively low white blood cell count and slow evolution of lung changes should cause one to suspect tularemia. It must also be considered in pleurisy with effusion.

SUMMARY

Three patients recovered from tularemic pneumonia, one case was complicated by encephalomeningitis. One patient with tularemic bronchitis with small pleural effusion also recovered.

CORONARY THROMBOSIS VS DISSECTING ANEURYSM IN DIFFERENTIAL DIAGNOSIS

L. MINOR BLACKFORD, M.D.

AND

CARTER SMITH, M.D.

ATLANTA, GA.

The clinical study of coronary thrombosis is one of the achievements of American medicine. First described by Herrick¹ in 1912, this condition has received so much attention in the past ten years that the diagnosis is probably rarely missed nowadays.

On the other hand, although dissecting aneurysm of the aorta was described more than 200 years ago, it is not a condition with which the average clinician is sufficiently familiar. Peery² has recently reported four cases, with a good discussion of the pathology. Interest in this subject has been active in Atlanta in recent years. Agnor³ has made a careful review of the literature and McGeachy and Paullin⁴ have published a clinical paper. According to these authors, about 500 cases have been reported but only nine were diagnosed during life. McGeachy and Paullin added three cases in which they recognized the condition at Grady Hospital.

REPORT OF CASE

A fat lawyer, aged 61, who had lived hard and worked hard, eaten hard and drunk hard, was sitting before an open fire after breakfast reading his Sunday paper. He was seized with a sudden severe pain, which caused him to cry out that something had "broken loose inside." The pain, it seems, began in the lower right quadrant of the abdomen, jumped to the lower

Fig. 1.—Tracing taken about two hours after the onset of pain. Although there are definite signs of myocardial damage there is nothing to suggest coronary thrombosis.

dorsal vertebrae and then settled over the xiphoid process. From this point it radiated up over the sternum to the base of the neck on each side. There was loss of sight in the right eye but this was transitory. One of us arrived within an hour of the first pain.

The patient was yelling with pain and presented a picture of moderate shock. The area of cardiac dullness was not enlarged and no retromammary dullness was made out. There was a harsh to and fro murmur over the base. The right hand was blue, and blood pressure could not be obtained in that arm. In the left arm the systolic pressure was 108 and the diastolic pressure 90. The pulse was 66. An opiate was administered at once. Although the first thought was of coronary thrombosis, the absence of a pulse in the right arm suggested an embolus to the right subclavian artery. The absence of pain in the right clavicular region and arm, however, made this seem improbable. The next thought was of aneurysm or of dissecting aneurysm. The patient was carried to his bed but he was in such agony that he refused to have his clothes removed.

In the early morning hours his wife had been awakened by a nightmare, and this had disturbed his rest. He had taken a large dose of salts, which resulted in a number of watery stools. He had not been to sleep since. It was learned that he had had a systolic blood pressure of over 200 and a diastolic of about 140 for several years. About fifteen months earlier he had been sick in another city with "acute indigestion," though his attending physician thought this was "heart trouble." He had been able to keep him in bed only two weeks. In recent months he had had several profuse hemorrhages from the nose.

Although he had been under the care of a physician at times for some years, he had never had any treatment for syphilis. His wife had never had a miscarriage and had borne him two healthy sons. This information and the absence of local signs rendered syphilitic aneurysm improbable.

After being placed in bed he complained of nausea and general abdominal distress in addition to the serious pain under the lower part of the sternum. He demanded ice water constantly and vomited at frequent intervals. Attempts at giving medicine by mouth were futile, and soluble phenobarbital, 5 grains (0.3 Gm.), was given by hypodermic. About two hours after the accident the blood pressure in the right arm was 84/64 and in the left arm 134/60. The pulse was still 66. By this time the diagnosis had been narrowed down to coronary thrombosis or dissecting aneurysm. He did not present a good picture of coronary thrombosis and yet the rarity of dissecting aneurysm caused us to favor the diagnosis of cardiac infarction.

An electrocardiogram was taken about two hours after the onset of pain. This showed marked slurring of the S wave.

in leads 1 and 2, with a low T wave in all three leads. There was a deep Q wave in lead 3, with a marked splitting of the QRS. The QRS in lead 4 was also slurred and the T wave was biphasic. This was interpreted as evidence of an incomplete bundle branch block with considerable myocardial damage, probably the result of the preceding hypertension. There was nothing in the tracings to indicate coronary thrombosis. Although in some cases it is several hours after the infarction before definite signs of coronary thrombosis appear in the electrocardiogram, when the onset is as sudden and severe as in this case signs of myocardial anoxemia at least should be present two hours later. Of course too coronary thrombosis could not interfere with circulation to the right arm. We therefore concluded that the diagnosis was dissecting aneurysm.

Ammophylline, 1 Gm., given twice intravenously was without effect. N-methyl-cyclohexyl-methyl-malonyleurea, also given intravenously, in small amounts put him to sleep with stertorous respiration, but only for a few minutes at a time. At 2:20 p. m., oxygen by nasal catheter was started. The restlessness and constant retching demanded extreme measures. At 4:45 Dr. Edgar D. Shanks, who had been called in consultation, advised dilaudid hydrochloride one-eighth grain

abdominal distress but it was difficult to limit the ice water. The second day the patient had been more comfortable than the first and we thought that perhaps he would recover. He had received great relief from the first enema and, the abdomen being tense and tympanic, we advised another. Just as this was started he gasped, and the face and neck turned purple. When examined a few moments later the heart sounds

Fig 2—The final rupture into the pericardium is emphasized by the finger. The irregular rupture into the media on the under surface of the arch is visible as well as the dissection of the innominate and right common carotid.

(0.008 Gm.), with atropine $\frac{1}{15}$ grain (0.0009 Gm.) by hypodermic injection. At this time blood pressure in the left arm was 130/88. At 7:20 respiration being only 10, 25 per cent solution of pyridine betacarboxylic acid diethylamide was given by hypodermic injection. This was repeated three hours later, when the respiration rate dropped to 8. He was awake again within an hour complaining of severe pain in the epigastrium.

At 1 a. m. dilaudid hydrochloride $\frac{1}{12}$ grain (0.002 Gm.), was repeated. In spite of this he woke up several times complaining of pain. The abdomen became greatly distended with gas. At 8:50 the blood pressure in the right arm was 120/80 and in the left arm 170/100. At this time the temperature was 100.4 and the pulse which had been slow before midnight, was up to 100. He was very nervous and restless, coughing frequently during the morning and vomiting occasionally. At 2:30 p. m. the blood pressure in the right arm was 144/104 and in the left arm 180/126. In contrast to the excruciating pain of the first day, he was relatively comfortable and it seemed that if the nausea, vomiting and 'gas' could be controlled he would be much better. A small enema resulted in the expulsion of a large amount of flatus. After this he began to perspire freely and to complain of epigastric pain. The pulse varied from 100 to 112.

At 4:45 p. m. the blood pressure in the right arm was 136/108 and in the left 176/96. It seemed that the large amounts of ice water he had been drinking might have contributed to the

were maudible. The oxygen tube was still in the nasopharynx and bubbles of gas escaped from his lips, a 25 per cent solution of pyridine betacarboxylic acid diethylamide was injected several times, twice into the heart but without effect.

Although improvement the second day had caused us to waver a little in the diagnosis of dissecting aneurysm the nature of the death convinced us that this diagnosis had been correct and that a second rupture had occurred.

AUTOPSY

The postmortem was performed two and a half hours after death. The contents of the abdomen were without interest.

Fig 4—Posterior view of the abdominal aorta showing the clean dissection of the media of almost the entire vessel below the level of the superior mesenteric trunk. It then extends partly down the left common iliac and all the way down the right common iliac.

except that the intestine was greatly distended with gas. When the pericardium was nicked bloody fluid gushed up several inches. A blood clot formed a cast of the heart. The heart though covered with fat was not enlarged and the coronary arteries looked normal. On the under surface of the arch of the aorta there was a transverse rupture into the media about 2 cm. in length. The dissection of the media had progressed so

that the thoracic aorta was practically a tube within a tube, and the final rupture was through a slit 8 mm long into the pericardium. The dissection extended up the right common carotid artery as far as we could follow it. The superior mesenteric trunk was also dissected down to where it was cut off and the dissection of the descending aorta went down the back of the aorta to its bifurcation, extending down 3 cm on the posterior surface of the right common iliac and below where the left common iliac was cut. Microscopic examination by Dr Warren B Matthews confirmed the diagnosis of medial necrosis.

COMMENT

The long history of hypertension, the agonizing, tearing pain as though something had been "torn loose inside," the temporary loss of vision, the nausea, the vomiting, the shock, the murmurs at the aortic region and the absence of pulsation in one extremity, the period of relative comfort with the dramatic death on slight effort, and the rupture into the pericardium in this case were all typical of dissecting aneurysm of the aorta, as McGeachy and Paullin have recently pointed out.

The diagnosis of dissecting aneurysm of the aorta should be made without difficulty, in most cases at any rate, if it is taken into consideration in differential diagnosis. It is important to make this diagnosis, for example, at the January meeting of the Southern Section of the Otological, Rhinological and Laryngological Society two cases were reported in which bronchoscopic examination had been done to determine the cause of dyspnea in cases of dissecting aneurysm with resultant rupture into the trachea. Although it would appear that the condition is rapidly fatal in perhaps 99 per cent of cases that come to autopsy, unquestionably it is not necessarily fatal; it may well be that recovery occurs much more often than this but because there is no autopsy in the case when death occurs years later, the diagnosis is lost. The most widely known case of recovery after dissecting aneurysm is that so beautifully pictured in successive editions of MacCallum's Text-Book of Pathology,* in this case a second rupture at a lower level from the pathologic lumen back into the aorta allowed the blood to be carried in two channels, and the second one was lined with endothelium at the time of death from an independent cause some years after the original accident. In spite of the rarity of the condition, therefore, it is exceedingly important to make the diagnosis to prevent too much being done and to keep the patient as comfortable and quiet as possible in the hope that he will recover with a double-barreled aorta.

SUMMARY

Dissecting aneurysm of the aorta occurred in a high-strung, hypertensive, fat man, aged 61, the diagnosis was definitely made before autopsy. Death occurred from rupture of the dissecting aneurysm into the pericardium thirty-six hours after the original break through the intima.

The diagnosis of dissecting aneurysm can be made and should be made in order to improve the patient's very slim chance of recovery.⁶

ROENTGEN STUDY OF A NONFATAL CASE OF BILATERAL TULAREMIC PNEUMONIA TREATED WITH SPECIFIC SERUM

STAIGE D BLACKFORD M D AND VINCENT W ARCHER M D
UNIVERSITY VA

The clinical and roentgenologic aspects of the pulmonary manifestations of tularemia have been discussed by us in previous communications.¹ In our series of thirty five unselected cases of tularemia, four of the seven patients with proved consolidation survived the illness. Tularemic pneumonia seemed more frequent and less fatal than previously recorded. However, the process has been unilateral in the nonfatal cases reported. In the present instance the patient recovered from bilateral tularemic pneumonia after administration of anti-tularemic serum. The pulmonary changes in this case have been studied over a period of two years by twenty nine roentgenograms.

Fig 1—Appearance Nov. 2, 1934, fifteenth day after onset of tularemia.

REPORT OF CASE

A Negro, aged 43, a gardener, was admitted to the hospital Nov. 1, 1934, in the afternoon in a semicomatose condition.

He had been well until about two weeks previously, when a severe continuous headache, a cough and a high fever had suddenly developed. About four days before admission he had become drowsy and irrational. The patient on examination was unusually well developed and somewhat obese. No abrasion of the skin or adenopathy was found. The only abnormality noted

Fig 2—Temperature curve with relation to anti-tularemic serum.

was the presence of numerous fine rales in the left apex anteriorly without other physical signs. The rectal temperature was 103.4 F and the pulse was 110 per minute. The urine contained a trace of albumin and from 3 to 5 red and from 3 to 5 white blood cells per high power field. The blood urea was normal. There was no anemia and the leukocyte count was

6,500 per cubic millimeter. Spinal fluid examination was negative. The diagnoses considered were (1) pneumonia of the left upper lobe, (2) tuberculosis of the left upper lobe and (3) typhoid.

The following morning stereoscopic films of the chest (fig 1) revealed a diffuse haziness over almost the entire left side of the chest. The density was much greater in the central portion than at either the apex or the base of the lung. On the right side of the chest there was much peribronchial thickening with

Fig 3—Appearance November 6

Fig 4—Appearance December 18

increased density at the hilus. The costophrenic angle was slightly hazy on both sides and there was some elevation of the left diaphragm. In a lateral view the density on the left side was seen to be centrally located extending anteriorly almost to the sternum. A diagnosis of a pneumonic process in the left lung was made and the roentgenologic report contained the suggestion that tularemia be considered as a possible cause of the consolidation.

On admission blood had been taken as a routine for culture for a Widal test and for agglutinations against *Brucella abortus*, *Bacillus proteus*, *Salmonella* and *Bacterium tularense*. Except for a three plus agglutination against *Bacterium tularense* in dilutions up to 1:20, these tests were negative when subsequently reported. After the roentgen study and agglutinations, it was ascertained that the patient had skinned a rabbit a few days prior to the onset of his illness. The antitularense agglutination reached a maximum titer of 1:640 two weeks later, but no ulcer or abnormal glands were ever found.

The only physical signs of consolidation were found in a small area of the left posterior portion of the chest for a few days shortly after admission. The temperature record during the febrile phase in the hospital is presented with relation to the specific therapy in figure 2. As soon as the fever disappeared the patient made a good convalescence clinically, gaining strength and weight. He was not allowed up, however, until three weeks later, and he was not discharged until he had been afebrile for four weeks because of the persistence of roentgenologic signs in the left lung. His subsequent progress was followed by outpatient visits Jan 2, Feb 16 and March 18, 1935, during which interval he gained much more strength and 26 pounds (12 Kg). He resumed light work March 26 and returned by request Dec 29, 1936 for roentgen study. He reported that for more than a year he had been feeling as well as ever.

To follow the course of the pulmonary changes roentgenograms of the chest were made almost daily during the febrile stage of the disease twice a week during the rest of the period

of hospitalization and on each subsequent outpatient visit. The original film Nov 2, 1934 (fig 1), has been discussed. A definitive pneumonic process in the right side of the chest was discernible November 6 (fig 3). Then the right side of the chest cleared gradually and the density on the left decreased, but even on December 18 (fig 4) there was still much haziness on the left side simulating a tuberculous pneumonia. In the films taken March 18, 1935 (fig 5), the left side of the chest was very much clearer. When the patient returned two years after discharge Dec 29, 1936 (fig 6), the stereoscopic films were thought to be within normal limits except for some questionable peribronchial thickening.

COMMENT

The contact history, the clinical course and the agglutinations substantiate the diagnosis of tularemia in this case. The absence of ulcers and abnormal glands is but further evidence in favor of Gudger's contention² that pulmonary lesions are apt to be prominent in the typhoidal type of the disease.

The most striking fact in this case is that the patient survived bilateral tularemic pneumonia following the administration of antitularense serum (Foshay). Recovery might have taken place in any event, but the gradual and prolonged decline in the temperature curve after the use of the serum certainly suggests that it was of value. Since the fever in tularemia is ordinarily sustained, its recurrence before final disappearance would seem

to indicate that its first decline was not spontaneous but rather due to serum therapy. The pulmonary changes could not have been followed accurately by the physical signs but were demonstrated satisfactorily by the serial films. The entire course of the pneumonic process on the right and the very slow resolution of the pneumonia already developed on the left were observed. There was a gradual but final complete absorption without marked residual change. At certain stages the appearance of the left lung was indistinguishable from that of a tuberculous consolidation.

Fig 5—Appearance March 18, 1935

Fig 6—Appearance Dec 29, 1936

SUMMARY

A patient with bilateral tularemic pneumonia treated with antitularense serum made a complete clinical recovery. The major radiologic changes in the chest were followed over a period of two years by serial roentgenograms. The extensive roentgenologic signs disappeared much more slowly than did the clinical symptoms.

AN UNUSUAL CASE OF A NEEDLE FOUND IN
THE HEART AT NECROPSYCHARLES REA M.D. AND PHILIP A. HOOVER M.D.
YORK, PA.

Although descriptions of foreign bodies in the heart are not common, neither are they unique. The literature contains reports of articles such as toothpicks, pins, needles, fish bones, bullets, shell fragments and in one case of a pipe stem¹ being lodged in the cardiac structure.

Bullets, especially in the post-war literature, are the foreign bodies most often reported. Keith² records eight cases in which fibrin-covered bullets were found free in the left ventricle.
